CHAPTER 41

Peripheral Blood Hematopoietic Cells for Allogeneic Transplantation

Norbert Schmitz[1] **and Peter Dreger**[2]

[1] Department of Hematology, Oncology and Stem Cell Transplantation, Asklepios Hospital St. Georg, Hamburg, Germany
[2] Stem Cell Transplantation Unit, Department of Internal Medicine V, University of Heidelberg, Heidelberg, Germany

Introduction

The existence of hematopoietic cells (HCs) in the peripheral blood (PB) was postulated in 1909 by Alexander Maximow [1]. In 1962, Goodman and Hodgson were first to prove that circulating HCs were capable of reversing irradiation-induced marrow aplasia in mice [2]. The first clinical transplantation was published in 1980 by Abrams et al., who transfused large numbers of syngeneic blood leukocytes to a patient with Ewing's sarcoma [3]. In 1985 and 1986, four different teams reported successful hematopoietic reconstitution by autologous blood-derived HCs in cancer patients [4–7]. Although these latter case reports provided the long-sought proof of principle, the low concentration of HCs in unmanipulated PB remained a major obstacle to the wider use of clinical transplants from PB, especially in the allogeneic setting where the exposure of healthy individuals to mobilizing cytotoxic drugs was not possible.

Only with the advent of granulocyte colony-stimulating factor (G-CSF) and the discovery that this and other cytokines were able to substantially increase the concentration of CD34$^+$ cells in PB [8,9] autologous and, 5–6 years later, allogeneic PBHC transplantation (PBHCT) began to enter the clinic. With regard to PBHCT, in 1989 Kessinger et al. showed that T-cell-depleted blood HCs were able to restore hematopoiesis after myeloablative therapy [10]. Because of fears that the high numbers of T lymphocytes contained in PBHC harvests would induce severe graft-versus-host disease (GVHD) in most recipients, allogeneic PBHCT replete of T cells was first used in emergency situations such as the failure of a previous marrow graft [11] or the inability of the donor to undergo general anesthesia for marrow collection [12]. After pilot studies using unmanipulated PB from human leukocyte antigen (HLA)-identical sibling donors were published in 1995 [13–15], a surge of allogeneic PBHCTs ensued. Currently, more than 70% of all allogeneic transplants in Europe and worldwide are performed with PB instead of marrow [16].

The donors

When allogeneic PBHCT entered the clinical arena, the experience with healthy individuals donating HCs mobilized into the blood was limited. The major issues that had to be addressed were the following:

1. How could HCs be harvested most effectively?
2. Did harvest products from the PB contain stem cells in quantities and quality that would allow for timely, complete, and durable engraftment of allogeneic lymphohematopoiesis?
3. What were the acute side-effects and long-term sequelae of the mobilization and collection procedure?

For further information regarding donors for HCT see also Chapter 39.

Mobilization and collection of HCs from PB

The first attempts to "mobilize" HCs into the PB of normal donors followed the experience gained with granulocyte transfusions, and with the mobilization of autologous HCs in patients with lymphoma and other diseases where the stem cell pool was not compromised by marrow infiltration or extensive cytotoxic therapy. G-CSF at doses between 5 and 16 μg/kg/day was administered to the potential donor for 5–7 days. Such treatment allowed the collection of CD34$^+$ cell numbers ranging from around 2 to more than 20×10^6/kg recipient body weight in most instances. Infusion of the harvest products into recipients with leukemia or lymphoma after myeloablative therapy resulted in reliable and surprisingly fast engraftment.

Tens of thousands of healthy individuals have now undergone mobilization and collection of PBHCs using a variety of harvest protocols. A joint analysis from the International Bone Marrow Transplant Registry (IBMTR) and the European Group for Blood and Marrow Transplantation (EBMT) [17] summarized the experience with 1488 donations of PBHCs from HLA-identical siblings (n = 1322), other relatives (n = 149), or unrelated donors (n = 15). Nearly all donors had received G-CSF (filgrastim, lenograstim) for mobilization. Approximately 40% of the donors had undergone a single apheresis, 45% underwent two, 11% underwent three, and 5% had to undergo four or more leukaphereses to collect the number of HCs deemed necessary for engraftment by the investigator. A single-center study reported on 400 related and unrelated donors who had received 10 μg/kg/day subcutaneously of glycosylated or non-glycosylated G-CSF once daily for 4 consecutive days, with apheresis commenced on day 5 [18]. The target cell number of 4×10^6 CD34$^+$ cells/kg was reached after one (63%) or two aphereses in 81% of donors. Most other donors collected between 2 and 4×10^6 CD34$^+$ cells/kg, while only 11 donors (<3%) collected less than 2×10^6 CD34$^+$ cells/kg with a maximum of two aphereses. Hoelig et al. reported on 3928 unrelated donors who had undergone stem cell harvesting in Dresden, Germany [19]. Of the donors, 97.3 % had received 7.5 μg/kg of lenograstim for 5 to 6 consecutive days. With

this schedule 99.5 % of donors collected enough CD34$^+$ cells (median 5.88 × 10^8 CD34$^+$ cells) in 1 or 2 leukaphereses. In female donors, a second leukapheresis had to be performed in 37.4 % of cases as opposed to 15.9 % of all collections in men.

Based on these and similar data, G-CSF at a dose of 7.5 to10 μg/kg given for 4 or 5 consecutive days is considered the standard regimen for mobilization of allogeneic HCs, although other G-CSF doses as low as 2 μg/kg or as high as 40 μg/kg given once or twice daily have been used for mobilization, with a clear trend towards higher CD34$^+$ cell numbers being collected after administration of higher doses of growth factor. Commencing leukapheresis on day 4 or 5 with any commercially available continuous flow blood cell separator will allow the collection of adequate numbers of HCs in nearly all healthy individuals with one or two daily collections if two to four times the donor's blood volume is processed. CD34$^+$ concentrations in PB decrease when G-CSF is continued for 7 days and beyond. Therefore, adequate timing of apheresis and effective collection procedures are key to achieve optimum harvest products. Other variables such as age, sex, body weight or baseline CD34$^+$ cell concentration in the blood of the donor have also been described to correlate with the stem cell yield, but these findings remain controversial, and none of these parameters will allow precise prediction of the stem cell yield.

More recently, pegfilgrastim, a covalently bound conjugate of filgrastim and monomethoxypolyethylene glycol with a significantly longer elimination half-life than unconjugated G-CSF, at a single dose of 12 mg, has been used to mobilize allogeneic PBHCs in healthy family and unrelated donors [20]. Adequate numbers of HCs for transplantation could be harvested from healthy donors mostly by a single apheresis. However, bone pain and headaches appeared to be more severe after injection of pegfilgrastim. Additional concerns were caused by the hyperleukocytosis and the spleen enlargement seen after administration of pegfilgrastim. Further investigations would therefore be needed before pegfilgrastim can be recommended for mobilization of HCs.

Growth factors other than G-CSF or its variants, mostly granulocyte–macrophage colony-stimulating factor in conjunction with G-CSF, have occasionally been used for mobilization in healthy individuals, with no obvious advantages over the administration of G-CSF alone. Interleukin-3 (IL-3) [21], stem cell factor [22], and other experimental cytokines like fms-related tyrosine kinase-3 (Flt3) ligand [23] have been shown to increase the CD34$^+$ cell concentration in the PB of rodents, primates or humans, but have never been used clinically because of their side-effects, which would put healthy volunteers at unnecessary and potentially severe risk.

Plerixafor is an inhibitor of chemokine (CXC) receptor-4/stromal cell-derived factor-1α (CXCR4/SDF-1α) interaction that mobilizes CD34$^+$ cells into PB. In normal volunteers, a single injection of plerixafor after 4–5 days of G-CSF resulted in a 3–3.5-fold increase of circulating CD34$^+$ cells. This agent has been successfully used in the autologous setting [24] but awaits further study in healthy donors.

The increasing use of non-myeloablative preparatory regimens, and of unrelated, mismatched and haploidentical donors, will call for high CD34$^+$ cell numbers to safeguard against the increased risk of graft failure associated with any of these procedures. It is for these reasons that the search for the optimum mobilization and collection procedure is ongoing.

Characteristics and dose of HCs from PB or marrow

As the human hematopoietic stem cell itself is still elusive, the precise answer to the question of how many hematopoietic stem cells are contained in a typical PB collection product awaits further study. It is, however, possible to describe the quality and quantity of committed and more immature HCs as they appear in G-CSF mobilized PB, and to compare the findings with marrow-derived HCs. This comparison would indicate that primitive and committed HCs are present in mobilized PB at least as frequently as in a typical bone marrow (BM) harvest. Using the CD34$^+$ antigen, which can easily be detected by flow cytometry, as a surrogate marker for the human stem cell, pilot studies found that G-CSF mobilized PB would contain two to five times more HCs than BM. This has been confirmed by the results of the large randomized trials [25–28].

What is the minimum CD34$^+$ cell number to guarantee quick and durable engraftment? And should a certain number of CD34$^+$ cells not be exceeded? A definite answer to both questions is not possible. However, it seems reasonable to recommend the collection of at least 2–4 × 10^6 CD34$^+$ cells/kg recipient weight, because clinical experience indicates that the risk of graft failure is increased if less than this threshold number is transplanted. It is also difficult to tell if there should be an upper limit for CD34$^+$ cell numbers and if higher numbers would be harmful if transferred to the recipient. Animal experiments [29] and clinical data indicate that the desirable number of HCs needed to ensure engraftment will depend on a number of interdependent parameters, the most important of which are the immunosuppressive potential of the conditioning regimen, the HLA disparity between donor and recipient, the number of T cells infused, and the regimen used for GVHD prophylaxis.

For a "standard" transplant from an HLA-identical sibling donor after myeloablative conditioning, doses between 4 and 10 × 10^6 CD34$^+$ cells/kg may be optimal, while other situations, for example haploidentical transplantation, will need much higher numbers of CD34$^+$ cells to secure engraftment. Higher CD34$^+$ cell numbers have generally been recommended because a significant correlation with improved survival has been demonstrated [30,31]. It probably is less important if high CD34$^+$ cell numbers come from BM or PB, although one study reported that rich marrow (containing >2.7 × 10^8/kg nucleated cells) may result in superior outcome compared with mobilized PB [32]. On the other hand, because PBHC collection products containing high CD34$^+$ cell numbers also contain more T cells, it has been postulated not to use transplants from PB with very high CD34$^+$ cell numbers. Przepiorka et al. evaluated risk factors for acute GVHD after allogeneic PBHCT and found a sharp increase of GVHD if more than 6.3–10.0 × 10^6 CD34$^+$ cells/kg were transplanted [33]. It will be difficult, however, to confirm this finding with prospective data because such high numbers of marrow or PBHCs are harvested from a small fraction of donors only.

A number of investigators have looked at immunophenotypically, genotypically, or functionally characterized subtypes of HCs in more detail. Körbling et al. reported that G-CSF at a dose of 12 μg/kg/day increased the concentrations of PB CD34$^+$ cells and more primitive subsets such as CD34$^+$Thy1^{dim} and CD34$^+$Thy1^{dim}CD38$^-$ cells by 16.3-, 24.2-, and 23.2-fold, respectively. The mean apheresis yield of CD34$^+$Thy1^{dim} and CD34$^+$Thy1^{dim}CD38$^-$ cells per kilogram of recipient body weight and per liter of donor blood processed was 48.9 × 10^4 and 27.2 × 10^4, respectively, indicating an additional "peripheralization" effect of G-CSF on primitive CD34$^+$ cell subsets [34,35].

Other reports confirmed these findings but also showed that the immunophenotypic profiles of HCs from blood or marrow differed in several respects (Table 41.1) (reviewed in [36]). The low expression of CD71 and the decreased retention of rhodamine-123 in CD34$^+$ cells from mobilized PB suggest that these cells are not actively proliferating or metabolically active [37]. Kinetic data corroborate the phenotypic findings, further demonstrating that

Table 41.1 Characteristics of $CD34^+$ hematopoietic cells (HCs) from bone marrow (BM) or mobilized peripheral blood (PB)

Characteristics	BM	Mobilized PB
Phenotype		
$CD13^+$, $CD33^+$	Standard	Higher
$CD38^-$	Standard	Higher
$HLA\text{-}DR^-$	Standard	Higher
$CD10^+$ $CD19^+$	Standard	Less
$CD7^+$	Standard	Less
c-kit	Standard	Less
VLA-4	Standard	Less

Genotype cell cycle progression	Standard	Less
DNA synthesis	Standard	Less
GATA 2		Increased
N-*myc*		Increased
Apoptotic activity		Increased

LTC-IC, long-term culture-initiating cells.

relatively more $CD34^+$ cells from PB exhibit characteristics of quiescent cells [38].

Steidl et al. [39] reported on the molecular phenotype of BM-derived and circulating $CD34^+$ cells from mobilized PB. Gene expression profiling confirmed that $CD34^+$ cells from BM cycle more rapidly, whereas $CD34^+$ cells from PB include more quiescent stem and progenitor cells.

Prosper et al. [40] investigated the number of long-term culture-initiating cells (LTC-ICs) in the PB of normal donors treated with G-CSF (7.5–10 μg/kg/day) and found that $CD34^+CD38^+$ cells and $CD34^+HLA\text{-}DR^+$ cells sorted from mobilized PB contained 0.5–5% of cells capable of sustaining hematopoiesis in long-term culture for up to 5 weeks. This is at least five times more than the number of LTC-ICs found in steady-state BM or non-mobilized PBHCs. However, 90–95% of the LTC-ICs present in $CD34^+CD38^+$ or $CD34^+HLA\text{-}DR^+$ fractions of mobilized PB were not able to sustain hematopoiesis for 8 weeks, as is the case with close to one-third of $CD34^+CD38^+$ and $CD34^+HLA\text{-}DR^+$ cells from non-mobilized PB. Plerixafor may mobilize more primitive precursors than G-CSF in normal donors; further differences in the cell content of collection products mobilized by G-CSF, plerixafor, or both, have been described [24]. It is not clear if these differences may influence clinical outcomes of patients transplanted with such cells.

Taken together, phenotypic, genotypic, and functional analyses of HCs from BM or G-CSF mobilized PB demonstrate that stem and progenitor cells are contained in both compartments. HCs from PB may be enriched in LTC-ICs and other clonogenic cells, they are metabolically less active, cycle less frequently, and show increased apoptotic activity. Stem cell biology including the differences of $CD34^+$ cells from mobilized PB or BM remains an area of active research because a better understanding of basic phenotypes and function is paramount to optimize the peripheralization, harvesting, and clinical use of HCs.

T lymphocytes and other immune cells in mobilized blood

There are many differences in the composition of PBHC harvests and marrow grafts if cells other than HCs are considered. Most importantly, PB harvests contain up to 10 times more T cells than BM; the ratio of $CD4^+$: $CD8^+$ lymphocytes, however, is identical. This had already been noticed with autologous PBHC harvests, and was the most important reason why investigators initially accepted allogeneic transplants with PB as an alternative to BM only hesitantly. To some extent, the numbers of T cells contained in PBHC harvests relative to the number of $CD34^+$ cells seem to depend on the mobilization protocol and the day of apheresis. Leukapheresis on day 5 after administration of G-CSF should give the highest stem cell yield with relatively low numbers of T cells contained in the final product. Plerixafor alone or in combination with G-CSF may be used to collect HCs from normal donors in the future but will require new schedules for stem cell harvesting to be developed in order to fully exploit the benefits such alternative collection methods may offer to donors and patients [24].

The observation that the high number of T cells in PB harvests did not lead to a dramatic increase in the incidence and severity of GVHD in patients allografted with mobilized PB prompted researchers to investigate the effects of G-CSF administration on the number and function of immune cells in more detail. With regard to T cells, Pan et al. [41] were first to show that pretreatment of healthy individuals with G-CSF polarizes T cells towards the production of type 2 cytokines (IL-4 and IL-10), while type 1 cytokine production (interferon-gamma and IL-2) is reduced. Other effects potentially explaining the unexpectedly low incidence of severe GVHD after transplantation of allogeneic PBHCs are the downregulation of allogeneic immune responses by post-transcriptional inhibition of tumor necrosis factor-alpha production [42], and the comobilization of $CD4^+$ and CD 8^+ T cells. Kusnierz-Glaz et al. [43] demonstrated that $CD4^+CD8^+$ αβ T cells are markedly enriched in the leukapheresis products of G-CSF-treated normal donors, and that these cells, further enriched in low-density fractions of mobilized PB, significantly suppress the mixed lymphocyte reaction. Regulatory T cells are thought to combat GVHD; studies with G-CSF mobilized PB showed upregulation of genes related to T helper type 2 (Th2) cells but also to T reg (Treg) cells [44].

Mielcarek et al. [45] calculated that the number of $CD14^+$ cells in mobilized PB was 50-fold greater than in marrow. These large numbers of monocytes suppress T-cell proliferative responses to alloantigen by increased IL-10 production and decreased secretion of IL-12 and tumor necrosis factor-alpha. Arpinati et al. demonstrated that the number of Th2 cell-inducing dendritic cells (pre-DC2s) was increased in mobilized PB. As pre-DC2s lead to polarization of naïve $CD4^+$ T cells toward a Th2 phenotype, this finding also may explain why transplantation of allogeneic PBHC does not lead to more severe GVHD in a larger fraction of patients [46].

Franzke et al. [47] showed that T cells do express G-CSF receptors after G-CSF treatment, and G-CSF can thus directly modulate T-cell immune responses. Among other possible mechanisms, G-CSF seems to diminish T-cell receptor-mediated activation and proliferation, downregulate leukocyte function associated antigen-1 alpha (LFA-1α) thus affecting the homing process of the graft and abrogating donor T-cell activation to host antigens, and upregulate GATA-binding protein-3 (GATA-3), the master regulatory factor for induction of a T helper immune response.

Natural killer cells are five- to 10-fold more frequent in mobilized PB than in BM. Joshi and colleagues analyzed peripheral blood mononuclear cells from G-CSF-mobilized blood cell harvests for their immunologic function and compared them with peripheral blood mononuclear cells from steady-state non-mobilized donors [48]. They found a significant decrease in NK- and lymphokine-activated killer cell-mediated cytotoxicity for G-CSF-mobilized effector cells. They also reported a significant decrease in both

T-cell and B-cell mitogen responses with G-CSF-mobilized versus non-mobilized cells. Neutrophils not only increase in number after administration of G-CSF, but their function also is enhanced immediately after G-CSF administration, as shown by upregulation of Fcγ RIII receptors, cell surface CD11b and CD66 molecules, and elevated levels of plasma elastase [49]. It is not finally clear which of the mechanisms described contributes to which extent to the striking observation that the infusion of 1 to 2 log more T cells into the recipient does not result in the development of severe GVHD in more patients grafted with PB.

Side-effects and long-term sequelae of mobilization and collection of HCs

The overall short- and long-term effects of G-CSF have repeatedly been reviewed. The acute toxicities of G-CSF administration have been well characterized, and comprise bone pain, headache, and fatigue as the most frequent side-effects. However, myalgias, chest pain, anxiety, insomnia, night sweats, fever, anorexia, weight gain, nausea and/or vomiting, and local reactions at the injection site have also been described [18,50]. Side-effects have been mild to moderate in the vast majority of donors and usually resolve within 48 hours of discontinuation of G-CSF. They can be treated successfully by the administration of minor analgesics (acetaminophen or ibuprofen) in most instances, and these side-effects have not been reported to require cessation of G-CSF administration or cancellation of the PBHC harvest. There is some indication that the frequency and severity of side-effects of G-CSF is dose dependent [51]. Therefore, doses as low as possible should be used.

A number of side-effects of G-CSF administration and the harvest procedure on blood chemistry, the coagulation system, and baseline hematologic parameters already described in patients with hematologic malignancies also occur in normal individuals. Laboratory abnormalities caused by G-CSF include transient increases of lactate dehydrogenase and alkaline phosphatase, uric acid, alanine aminotransferase, and/or glutamyl transpeptidase, and a decrease in serum potassium and/or magnesium [52].

Several authors have shown that G-CSF can induce a mild hypercoagulation state, as indicated by in vitro testing. Increases in fibrinogen and factor VIII levels, a reduction in protein C and S levels [53], and increases in prothrombin fragments, thrombin–antithrombin complexes, D-dimers, and platelet aggregation have all been reported [54–56]. Mild-to-moderate decrements in platelet, lymphocyte, and granulocyte levels have been described following the collection of PBHCs [57]. Thrombocytopenia may partly be due to the administration of G-CSF itself or the leukapheresis procedure. Cytopenias are usually mild and self-limited, although more profound thrombocytopenia following repeated large-volume leukaphereses has been reported.

A number of studies have been presented that compare the experience of donors who participated in one of the randomized trials comparing BM transplantation (BMT) with PBHCT [58–63]. A Cochrane review [64] summarized the findings of six randomized trials comparing the tolerability and safety of hematopoietic stem cell donation from blood or marrow. It was reassuring that none of these reports described life-threatening complications or long-lasting discomfort in any of the donors. The study reports generally confirm that the side-effects of PBHC harvesting are related mainly to G-CSF administration, while the side-effects of BM harvesting are caused by the harvest procedure itself. The incidence of adverse events occurring in 5% or more of donors of PB or BM who participated in the large European trial are presented in Table 42.2.

Table 41.2 Subject incidence of adverse events occurring in >5% of donors. Date from the EBMT study comparing bone marrow transplantation (BMT) with peripheral blood progenitor cell transplantation (PBPCT) [28]

	BM donors (n = 166)	PBHC donors (n = 164)
Any adverse event	95 (57%)	107 (65%)
Harvesting procedure-related adverse events		
Any harvest-related	91 (55%)	61 (37%)
Access pain	39 (23%)	2 (1%)
Anemia	17 (10%)	0 (0%)
Back pain	16 (10%)	4 (2%)
Nausea	10 (6%)	1 (1%)
Arthralgia	8 (5%)	1 (1%)
Vomiting	8 (5%)	0 (0%)
Skeletal pain	3 (2%)	10 (6%)
Filgrastim-related adverse events		
Any filgrastim-related		96 (59%)
Musculoskeletal		71 (43%)
Headache		19 (12%)
LDH increased		14 (9%)
Alkaline phosphatase increased		8 (5%)

BM, bone marrow; LDH, lactate dehydrogenase; PBHC, peripheral blood hematopoietic cell.

Some of these studies also measured the emotional status and pain of donors prior to the harvest procedure and at defined time points after the collection of BM or PB. In general, the symptom burden, the levels of maximal and average pain, fatigue, and anxiety were similar, although symptom peaks occurred at different time points during G-CSF administration (in PB donors) or shortly after BM harvesting. A quicker resolution of symptoms in PBHC donors was also described [59,60]. Only the Scandinavian trial reported a significant difference in the total burden of complaints in the two groups of donors, favoring the PB donors. This study also found that donors would prefer to donate PB rather than BM if asked to donate again [61]. This observation is in line with reports from unrelated donors.

Serious or lethal complications of G-CSF administration and leukapheresis are rare. At least five cases of splenic rupture associated with the harvest procedure have been reported [65–69]. Therefore, special attention should be paid to donors presenting with an enlarged spleen or a history of splenic disorders. Routine abdominal ultrasound has been recommended to reduce splenic complications. Also, cases of severe cardiovascular events [70], acute lung injury [71], acute iritis [72], pyogenic infections [73], gouty arthritis [74], and anaphylactoid reactions [75] have been reported.

Such case reports, as well as concerns that G-CSF may perturb normal hematopoiesis and increase the risk for developing malignant disorders of the blood, including myelodysplasia and leukemia, caused investigators to propose an international donor registry many years ago. A number of reports on acute and long-term events in large cohorts of donors have been published [19,69,76,77]. Overall, acute and severe complications of PB stem cell donation are rare (<1%) and differences in long-term side effects after donation of BM and PB were not detected.

The report by Halter et al. [69] summarizes all deaths and severe complications of PB or marrow donations for 51,024 recipients receiving a first HCT. Data were generated retrospectively from questionnaires sent out to the principal investigators of 338 transplant centers who participated in the annual EBMT activity surveys. Any serious event occurring within 30 days after donation and the occurrence of any hematologic malignancy in a donor had to be registered. Overall, five donor deaths occurred (one after BM and four after PB donation; incidence 0.98 per 10,000 donations) and 37 severe complications (12 in BM and 25 in PB donors; $p < 0.02$) were reported. Nineteen hematologic malignancies (8 after BM and 11 after PB donation; $p = 0.4$) were reported. Three deaths (pulmonary embolism, subarachnoidal hematoma, and cardiac arrest) were clearly related to the donation, whereas two cardiac arrests on days 15 and 17 after PB donation may or may not have been related to the harvest procedure. The severe, potentially life-threatening complications mostly were cardiovascular events, hemorrhages, and splenic rupture. The hematologic malignancies reported were acute myeloid leukemia (three), acute lymphoblastic leukemia (three), lymphoma (seven), nasopharyngeal plasmacytoma, chronic lymphoblastic leukemia, and myeloproliferative syndrome (one case each), and other non-specified disorders.

In Chapter 37, Confer et al. summarize data available on deaths that occurred worldwide after donation of BM or PB. It is unclear how much overlap might exist between their cases and those reported by Halter et al. Also, it remains uncertain what number of donations formed the basis to Confer's report. In any case, these data, together with the reports from other registries, suggest that life-threatening and fatal accidents are rare but do occur in donors of PB or marrow stem cells. No significant differences between PB and marrow donors regarding the long-term consequences of both harvest methods have been described.

The leukapheresis itself is generally well tolerated, but side-effects caused by the anticoagulant and placement of central venous access have been reported. Although an effort should be made to avoid a central venous access, 2–7% of donors ultimately will need it because peripheral veins cannot be used or the necessary blood flow cannot be established [13–15]. Rarely, donors have experienced tetany or severe symptoms of hypocalcemia caused by the anticoagulant used throughout the leukapheresis procedure.

The recipients

In 1995, pilot studies from the United States and Europe [13–15] indicated that transplantation of allogeneic PBHCs resulted in fast and stable engraftment; GVHD did not seem to occur more frequently than after marrow grafting. Larger series from other transplant centers or cooperative groups, as well as retrospective comparisons with BMT confirmed that transplantation of allogeneic mobilized PB seemed a viable alternative to marrow transplantation.

The largest retrospective analysis presented by IBMTR and EBMT compared results of 288 PBHCTs with 536 BMT procedures from HLA-identical sibling donors [78]. The paper confirmed that recipients of PBHCs attained more rapid recovery of neutrophils and platelets; significant differences in relapse rates and the incidence of grade II–IV acute GVHD between marrow and PBHCT were not observed. The incidence of chronic GVHD at 1 year, however, was significantly higher after PBHCT (65%) than after BMT (53%). Treatment-related mortality was lower, and leukemia-free survival rates were higher with PBHCT in patients with advanced leukemias, but were comparable in standard-risk leukemias.

Randomized trials in leukemia patients with HLA-identical family donors

Between 1998 and 2002, the results of eight prospective randomized trials comparing the transplantation of allogeneic PBHCs with that of BM were published [25–28,79–82]. These studies were almost exclusively done in patients with leukemia, patients with other hematologic malignancies were included only rarely, and non-malignant disorders were not represented at all. The donors were HLA-identical siblings, and BM or PBHCs were infused without any manipulation. The trials differed substantially with respect to the number of patients included, the status of the diseases, the mostly myeloablative conditioning regimes used, the doses of HCs and T cells infused, the GVHD prophylaxis administered, and a number of other variables that may have influenced outcome. Still, the results of these trials allow a number of important conclusions, which are summarized later.

Engraftment

Transplantation of allogeneic PBHCs results in faster engraftment of HCs of all lineages compared with BMT. Neutrophils exceed a threshold of 0.5×10^9cells/L between 2 and 6 days earlier with PBHC than after BMT. In the United States trial, the neutrophils surpassed 0.5×10^9/L on day 16 (range 11–29 days) with PB, and on day 21 (range 13–36 days) with BM ($p < 0.001$) [25]. The Canadian study reported neutrophil recovery on day 19 (range 12–35 days) with PB, and on day 23 (range 13–68 days) with BM [27]. Patients in the EBMT study had the shortest time interval from transplantation to an absolute neutrophil count of greater than 0.5×10^9/L: 12 days for PB and 15 days for BM [28]. However, this trial was the only one of the large randomized studies that used G-CSF (5 μg/kg/day) also after transplantation, and day 11 methotrexate was not included. Other randomized trials proved that the administration of G-CSF at a dose of 10 μg/kg/day after PBHCT can accelerate neutrophil recovery by 3–4 days.

Platelet recovery after allogeneic PBHCT is also faster by approximately 6 days: a platelet count of 20×10^9/L was reached on day 13 (range 5–41 days) with PB, and on day 19 (range 7–74 days) with BM in the US study ($p < 0.001$). The Canadian study reported platelet recovery after 16 (range 0–100) days for patients grafted with PB, and 22 (range 0–100) days for patients grafted with BM ($p < 0.0001$). The EBMT study had a median time to platelet recovery greater than 20×10^9/L of 15 days for patients transplanted with PB, and 20 days for patients transplanted with BM ($p < 0.0001$). This difference translated into a median of 8 (range 1–68) days of platelet transfusions in the PBHCT group, and a median of 10 (range 2–71) days in the BMT group ($p = 0.0029$).

It is well recognized that factors other than the source of HCs influence the pace of hematologic recovery. While G-CSF accelerates neutrophil recovery, methotrexate if given for prophylaxis of GVHD retards hematopoietic reconstitution [83]. The occurrence of GVHD, infection, the grade of genetic disparity between recipient and donor, and splenomegaly have all been reported to affect the speed of hematopoietic recovery, and may explain the slight variations in times to neutrophil and platelet recovery seen in the randomized trials. Graft failures after PBHCT are less frequent than after BMT particularly in situations where the risk of graft failure is increased. Comparative studies of hematopoietic chimerism after PBHCT and BMT support the notion that transplantation of PB results in fast, complete, and durable complete chimerism.

There is evidence that mobilized PBHCs in comparison to BM require less vigorous conditioning of the host to ensure full lymphohematopoietic chimerism. This essential feature of PBHCs was the basis for the introduction of reduced-intensity conditioning PBHCT making HCT the only potentially curative procedure for many hematologic malignancies occurring in older and comorbid patients.

Immune recovery

Recovery of immunity after unmanipulated allogeneic PBHCT is at least as quick as after BMT, but may be faster with respect to some subgroups of cells with immune functions. Circulating naïve

($CD4^+CD45RA^+$) and memory ($CD4^+CD45RO^+$) helper T cells, B cells, and monocytes are found in higher numbers after PBHCT compared with BMT between 1 and 11 months post-transplant [84]. Natural killer cell numbers did not significantly differ between patients grafted with PB or marrow over the same time period. Proliferative responses to T- and B-cell mitogens (phytohemagglutinin, pokeweed mitogen, tetanus toxoid, and *Candida*) were significantly increased in recipients of PB from HLA-identical donors [84].

Storek et al. [85] studied 115 patients who had been randomly assigned to receive allogeneic marrow or mobilized PB from HLA-identical donors. Between 1 month and 1 year after transplantation, the counts of $CD4^+CD45RA^{hi}$ and $CD4^+CD45RA^{lo/-}$ T cells were significantly higher after PBHCT. T cells appeared equally functional when challenged by phytohemagglutinin or herpes virus antigen. Median serum immunoglobulin G levels were similar in both groups of patients. Of note, the authors also reported that particularly severe infections were significantly reduced after PBHCT. The reduced risk was most prominent for fungal infections, intermediate for bacterial infections, but low for viral infections. This latter phenomenon may be a consequence of the marked loss of memory T cells that occurs after allogeneic PBHCT [86].

Another interesting observation published by Lapierre et al. [87] was that, 30 days after PBHCT, anti-A and/or anti-B blood group titers were significantly higher after PBHCT compared with BMT, suggesting that immune hematologic reconstitution after PBHCT is quicker than after BMT. This observation could explain the cases of acute hemolysis described after ABO-incompatible PBHCT. On the other hand, transfusion requirements are no different in ABO-, rhesus- or Kell-different transplantation; however, ABO-mismatched patients were reported to show poorer survival than matched patients after PBHCT.

Acute GVHD

The incidences of acute GVHD grades II–IV were similar for both groups of patients in all larger studies except for the largest one [28], which noted a 13% increase of grade II–IV acute GVHD ($p = 0.013$) and a 12% increase of grade III–IV acute GVHD with PB ($p = 0.0088$) (Table 41.3). The EBMT study also was the only study where the maximum grade of acute GVHD was the primary endpoint, and randomization was stratified for some of the known risk factors of GVHD. Other differences in the design of the EBMT study and the other trials were the inclusion of good-risk patients only, the omission of methotrexate on day 11, and the use of G-CSF post-transplant. Omission of day 11 methotrexate has been reported to predispose recipients to develop GVHD [83], although this finding was not supported by data from the international meta-analysis [88]. It also remains in question if the high numbers of T cells transferred with a typical PBHC graft are responsible for the higher incidence of acute GVHD. Although such a correlation between GVHD and T-cell numbers was detected in the EBMT study, another study failed to demonstrate such a correlation [89].

Chronic GVHD

The large randomized studies all showed at least a trend to more chronic GVHD with PBHCs, and two studies reported statistically significantly more chronic GVHD after PBHCT [26,28] (Table 41.4). There was also more extensive chronic GVHD in patients having received PBHCs compared with BM cells. This difference was significant in the EBMT trial and in the studies chaired by Blaise et al. [26] and Vigorito et al. [82].

Follow-up reports from the United States [90], the French [91], and the EBMT [92] trials were first published with a median follow-up of 41, 45, and 36 months, respectively. Flowers et al. still did not observe more chronic GVHD after PBHCT, and the clinical characteristics of chronic GVHD were similar after PBHCT or BMT [90]. However, the study showed that chronic GVHD was more difficult to control when it occurred after PBHCT compared with BMT: the number of successive treatments needed to control chronic GVHD was higher after PBHCT, and the duration of glucocorticoid treatment was also longer ($p = 0.03$ for both endpoints). In contrast, Mohty et al. found a highly significant difference in the 3-year cumulative incidence of chronic GVHD in the PBHC group compared with the BM group (65% vs. 36%; $p = 0.004$) [91]. They also observed significantly more extensive chronic GVHD. Chronic GVHD needed further immunosuppression and led to longer periods of hospitalization. The 3-year follow-up of the prospective EBMT trial (Table 41.4) and the 5-year follow-up of the retrospective IBMTR/EBMT study also showed more chronic GVHD in patients after PBHCT [93]. Recently, the US study [94] and the EBMT study [95] have been updated again with median follow-ups of 12.2 and 10.8 years, respectively. Whereas the investigators from the United States still did not find a significant different in the cumulative incidence of chronic GVHD or the need for systemic

Table 41.3 Acute graft-versus-host disease (GVHD) grades II–IV

Reference	PB (%)	BM (%)	*p*-value
Bensinger *et al.* [25]	64	57	$p = 0.35$
Blaise *et al.* [26]	44	42	Not given
Couban *et al.* [27]	44	44	$p = 0.9$
Heldal *et al.* [79]	21	10	Not given
Powles *et al.* [81]	50	47	Not given
Schmitz *et al.* [28]	52	39	$p = 0.013$
Vigorito *et al.* [82]	27	19	$p = 0.53$

All percentages represent cumulative incidences at day +100 post-transplant except for the studies by Blaise *et al.* [26], Heldal *et al.* [79], and Powles *et al.* [81] where the actual percentage of patients with acute GVHD at day +100 is given.

immunosuppression, the EBMT study again reported more chronic GVHD necessitating prolonged immunosuppression in patients transplanted with PBHCs. In both studies, however, overall survival of patients grafted with BM or PM did not significantly differ.

Relapse rates

Knowing that the graft-versus-leukemia effect is exerted mainly by donor T cells and that around 10 times more T cells are transferred with a typical PB collection product, it was anticipated that transplantation of PB cells would result in a reduction of relapse rates after PBHCT. Animal studies [96] and results of non-randomized studies also pointed in that direction. The randomized studies have not consistently confirmed these expectations so far, although the updated US study [94] and the small British study [81] reported significantly fewer patients with relapse after PBHCT than after BMT.

Transplant-related mortality

Retrospective analyses had suggested a trend in favor of lower transplant-related mortality (TRM) after PBHCT. Specifically, the EBMT/IBMTR study showed a significant advantage in TRM for patients transplanted with PB for advanced leukemias [78]. The randomized US study reported a cumulative incidence of transplantation-related deaths of 21% in the PB group and 30% in the BM group; this difference, however, was not significant [25]. The Canadian study also found a reduction in non-relapse deaths after PBHCT as opposed to BMT. At day 100 after transplantation, the actuarial probabilities of death were 7.4% for the PB group and 16.1% for the BM group, respectively (p = 0.07) [27]. Until now, significant differences have not been reported from any of the randomized studies, and it remains to be determined if subgroups of patients with specific diseases or disease status benefit from the transplantation of PB because TRM is reduced.

Survival

Survival is the most relevant endpoint of studies comparing BMT with PBHCT. This is particularly true because different sources of HCs may have different effects on secondary endpoints such as TRM, relapse rate or GVHD, and the interplay of these may give different results for overall survival if different clinical situations are considered.

At first presentation, the three largest randomized studies came to somewhat different conclusions with respect to survival. The EBMT study had overlapping survival curves for patients grafted with PB or BM [28]. The US study reported a difference in overall survival of 12% at 2 years between the two groups of patients, favoring PBHCT; this difference was borderline significant (p = 0.06) [25]. The subgroup of patients with more advanced disease had a statistically significantly better survival (57%) with PB than with BM (33%) (p = 0.04). The Canadian study reported better overall survival for the whole group of patients transplanted with PB (68%) compared with the BMT group (60%) at 30 months (p = 0.04). With longer follow-up neither the US study nor the EBMT showed any significant difference in overall survival [94,95]. However, the US study still found superior disease-free survival after PBHCT.

Marrow or mobilized blood: the meta-analysis

An individual-patient data meta-analysis using data from nine randomized trials enrolling 1111 adult patients has been published [97]. The study confirmed that PBHCT results in faster neutrophil and platelet engraftment than BMT. PBHCT was shown to cause more grades III–IV acute GVHD, and more overall and extensive chronic GVHD (68% vs. 52% at 3 years; $p < 0.000001$) compared with BMT (Figure 41.1). PBHCT decreased relapse rates in both late-stage (33% vs. 51% at 3 years; $p = 0.02$) and early-stage (16% vs. 20% at 3 years; $p = 0.04$) disease. Non-relapse mortality was no different between PBHCT and BMT. Overall survival and disease-free survival were only significantly improved in patients with late-stage disease (overall survival 46% vs. 31% at 3 years; $p = 0.01$). The major results of the meta-analysis are depicted in Figure 41.2. The study also made clear that the vast majority of data (75%) comparing PBHCT with BMT were generated in patients with early disease (CML in chronic phase, AML and acute lymphoblastic leukemia in first complete remission, and early MDS) and that CML – a diagnosis hardly treated by allogeneic transplantation in first chronic phase

nowadays – was the most frequent diagnosis (approximately 40% of all patients treated).

Mobilized BM for allogeneic transplantation

Several investigators have used G-CSF-stimulated BM for hematopoietic reconstitution after myeloablative therapy, and compared engraftment and the development of GVHD with patients who were rescued with G-CSF-mobilized PB [98]. A small prospective study (57 patients being randomized) comparing G-CSF-primed BM with G-CSF-mobilized PBHCs concluded that engraftment after transplantation of either source of HCs was comparable; however, more steroid-refractory acute GVHD, chronic GVHD, and prolonged requirement for immunosuppressive therapy was found after PBHCT [99]. Survival did not significantly differ. Larger randomized studies would be needed to clearly define the role of G-CSF-stimulated BM compared with G-CSF-mobilized blood.

Allogeneic PBHCT in diseases other than leukemia

The prospective studies comparing BMT with PBHCT, as well as most retrospective analyses, included patients with leukemia and a few with lymphoma or myeloma. It is therefore largely unknown how patients with diseases other than leukemia would fare after either procedure. Some years ago, EBMT published their experience with BMT or PBHCT in patients with MDS [100]. The results of this retrospective study were similar to the large retrospective analysis of patients with acute leukemias and CML published by the IBMTR and EBMT: earlier hematopoietic recovery, and similar incidences of acute, but more chronic GVHD with PB. The 2-year TRM was significantly reduced with PB except for patients who had refractory anemia or high-risk cytogenetics. Treatment failure was significantly decreased with PB. Estimates of the 2-year event-free survival were 50% with PBHC versus 39% with BM. Gahrton et al. compared PBHCT with BMT in patients with multiple myeloma [101]. They did not find significant differences between BMT and PBHCT for TRM, acute and chronic GVHD, progression-free survival or relapse rates; overall survival tended to be better in the BMT group (53% vs. 44% at 3 years; $p = 0.05$).

Another EBMT study compared outcomes of 692 patients with severe aplastic anemia grafted with either mobilized blood or marrow from HLA-matched sibling donors. Hematopoietic recovery and grade II–IV acute GVHD were similar after PBHCT and BMT. In patients aged over 20 years, chronic GVHD and overall mortality rates were similar after PBHCT and BMT. In patients aged 20 or less, however, rates of chronic GVHD and overall mortality were higher after transplantation of PBPC than after BMT. In younger patients, the 5-year probabilities of overall survival were 73% and 85% after PBHCT and BMT, respectively. Corresponding probabilities for older patients were 52% and 64% [102]. These and other data for unrelated [103] or related donor transplants [104] indicate that BM grafts should be preferred to PBHCT in patients with severe aplastic anemia, and that results of PBHCT versus BMT may vary according to the underlying disease. No comparisons of BMT with PBHCT are available so far for patients with lymphoma.

Allogeneic PBHCT in children and adolescents

A study from the IBMTR cautioned against the use of PBHCT in children and adolescents [105]. One hundred and forty-three PBHCT and 630 BMT procedures from HLA-identical sibling donors in patients aged 8–20 years with acute leukemia were compared. Risks of grade II–IV acute GVHD were similar; however, the incidence of chronic GVHD was higher after PBHCT. The cumulative incidences of chronic GVHD at 3 years were 33% and 19% after PBHCT and BMT ($p = 0.001$). In contrast to reports in adults, rates of TRM, treatment failure, and mortality were also higher after PBHCT. The 3-year probability of overall survival, adjusted for other significant factors, was 48% and 58% after PBHCT and BMT, respectively ($p = 0.01$). These data serve as a cautionary note before a major change in the source of HCs used for allogeneic transplantation of children comparable to the situation in adults will occur. Cord blood is an attractive alternative, particularly for children (see Chapter 39) and prospective studies comparing cord blood transplantation, BMT, and PBHCT would be helpful to better define the role of the various sources of HCs.

T-cell-depleted mobilized blood

Because of concerns that the large numbers of T cells contained in mobilized PB would cause more frequent and severe GVHD, the interest in T-cell-depletion strategies was high from the beginning. Soon after the first transplants with mobilized PB had been reported, a number of studies using T-cell-depleted mobilized PB were initiated. Early results, however, were disappointing because – among other causes – depletion methods were far from optimal. With T cell numbers in excess of 1×10^5 T cells/kg recipient body weight remaining in the graft, it was not too surprising that acute and severe GVHD still occurred with incidences comparable to those observed after transplantation of unmanipulated PBHCs.

With further experience, technical problems were solved, and it became possible to routinely purge PB collection products to a residual T-cell content of below 1×10^4 T cells/kg. Such minimal T-cell load is not sufficient to elicit clinical GVHD even in the haploidentical setting. One of the major problems of T-cell depletion at the time when BM was exclusively used as the source of HCs was the increase in graft failures occurring after transplantation. Because CD34$^+$ cell numbers are much higher in mobilized PB, and the eventual loss of HCs caused by the depletion process can be compensated for by further leukaphereses, graft failure is less of a problem after the transplantation of T-depleted mobilized PB. Urbano-Ispizua et al. reported that the graft failure rate was still 18% after T-cell-depleted PBHCT if fewer than 2×10^5 CD3$^+$ T cells remained in the graft, while the incidence was very low (1%) if more than 2×10^5 T cells were infused [106]. It should be noted, however, that in this study relatively low numbers of CD34$^+$ cells (3.4×10^6/kg) had been infused into patients who subsequently suffered graft failure. Other studies suggest that the transplantation of very high numbers of CD34$^+$ cells can overcome the graft failure risk in the HLA-identical and the mismatched setting regardless of the residual number of T-cells in the graft.

Transplantation of CD34$^+$-selected cells from mobilized PB to patients with early myeloid malignancies was reported to result in less GVHD, less TRM, and better disease-free survival if compared with unmanipulated PBHCT. The randomized study published by Cornelissen et al. [107] made clear that the results of CD34 selection of PB or marrow are largely dependent on the efficacy of the T-cell-depletion strategy. With current methodology, high CD34$^+$ cell numbers can be transplanted after effective T-cell depletion ($<1 \times 10^5$ T-cells /kg recipients weight). Using such grafts can result in high overall and disease-free survival of patients grafted for early AML [108,109].

In summary, the availability of HCs from PB is important in the context of T-cell depletion strategies, because GVHD nowadays can virtually be eliminated by vigorous depletion strategies without a dramatic increase of graft failure rates when high to very high numbers of HCs are transferred. T cells, however, are mediators of the graft-versus-leukemia effect and contribute to quick immune reconstitution after transplantation. For these reasons, transplantation of T-depleted mobilized blood has often been restricted to cases of haploidentical transplantation where high numbers of CD34$^+$ cells are needed.

Unrelated donor transplants

Retrospective reports comparing PBHCT with BMT reported faster engraftment with PB; severe acute GVHD, 1-year TRM, and overall survival did not significantly differ after PBHCT or BMT but patients transplanted with PB experienced more cGVHD [110,111]. Recently, the first prospective randomized study comparing allogeneic PBHCT with BMT has been published [112]. The study enrolled 551 patients below the age of 66 years. Most patients suffered from acute myeloid or lymphoblastic leukemia or myelodysplastic syndrome. At 2 years, the overall survival (51% after PBHCT, 46% after BMT) did not significant differ. The overall incidence of graft failure was significantly higher after BMT (19% vs. 3% after PBHCT). The incidence of chronic GVHD in the PBHCT group was 53% as compared to 41% in the BMT group ($p = 0.01$). There were no significant differences in the incidence of acute GVHD or relapse. The authors conclude that PBHCT may be preferable over BMT if graft failure is the major clinical threat and BMT may be the better source of HCT in other settings. Also after publication of this important study, the clinician is left with more questions than answers: the study was largely restricted to patients with leukemia and MDS which were unsatisfactorily classified into good- or poor-risk disease by clinical parameters only (no cytogenetic or molecular characterization of the disorders are reported), GVHD prophylaxis probably was suboptimal in a significant proportion of cases who in 2013 would be considered mismatched transplants, and follow-up was still too short to allow for final conclusions.

Conclusion and future developments

A clear-cut picture of the advantages and disadvantages of G-CSF administration and collection of HCs from PB has evolved over recent years. Long-term side effects of PBHC and marrow harvesting do occur and make close follow-up of donors necessary. This is particularly an issue because the demand for HCs will steadily increase, and a rising number of older recipients and donors with comorbidities will be involved. Many potential donors and medical community members currently prefer to work with HCs from PB. This is a consequence of the results of the clinical trials available so far, but is also dictated by recent developments in other areas of blood and marrow transplantation, including non-myeloablative conditioning, exhaustive T-cell depletion, and transplantation across major HLA barriers, all of which require high to extremely high numbers of HCs that usually cannot be harvested from BM.

In the near future, patients will likely receive cocktails of HCs plus an array of other cells with distinct immune functions tailored to each patient's needs. Probably, all of these cells will be harvested or grown from the PB. One of the most exciting questions today is whether, with our increased understanding of basic immunology, it will be possible to dissect GVHD from the graft-versus-leukemia effect, both exerted by donor T cells. Future work will also show if blood can act as a source of truly pluripotent stem cells that can be used in the treatment of non-hematopoietic diseases, including cardiac failure, Parkinson's disease, and other degenerative disorders.

CHAPTER 42

Cryopreservation of Hematopoietic Cells

Scott D. Rowley
John Theurer Cancer Center, Hackensack University Medical Center, Hackensack, NJ, USA

Introduction

Storage of hematopoietic cells (HCs) is required for transplantation, whether for the brief period required to deliver a freshly harvested bone marrow (BM) or peripheral blood HC (PBHC) product to an allogeneic recipient, or for the long-term (potentially decades) banking of cord blood HCs (CBHCs) intended for unrelated-donor transplantation. Room temperature or refrigerated (4 °C) storage may be appropriate for products stored for a few hours to a few days. Cryopreservation allows longer term storage and is the storage technique for virtually all products intended for autologous HC transplantation (HCT). Although cryopreservation of HCs is not a requirement for treatment with myeloablative, dose-intensive conditioning regimens, and patients have recovered marrow function after reinfusion of HCs stored for several days at 4 °C, a progressive loss of HCs occurs during non-frozen storage. The definition of ideal conditions (e.g., temperature of storage, initial processing of the cells, cell concentration, and additives) for the non-frozen storage of cells may slow this loss. In contrast, although some unavoidable loss of HCs occurs with processing and cryopreservation, progressive loss over months to years of proper storage is not obvious and may not occur if optimal storage conditions are maintained.

It is evident that HCs can be successfully cryopreserved from the successes of autologous and allogeneic HCT in regenerating marrow function after myeloablative conditioning regimens. Although some investigators have correlated poor HC cryopreservation with delayed engraftment after transplantation [1,2], this deleterious effect is most likely to be observed with products containing borderline quantities of HCs. Most cryopreservation laboratories use a variation of the technique outlined in Table 42.1, including differences in cryoprotectant concentration, product volume, and storage temperature. Although easily performed, HC cryopreservation and reinfusion are not without risk of toxicity to both the HC inoculum and the recipient of these cells. There are multiple aspects to successful cryopreservation of HCs. Each of these variables affects the survival of the cells and, as with any manufacturing process, must be rigidly controlled for reproducible results.

Non-frozen storage of HC products

Cryopreservation is not required for short-term storage of HCs. Non-frozen storage is a less costly alternative, especially for the immediate transportation of products and for the transplantation of patients conditioned with brief courses of chemotherapeutic agents with short in vivo half-lives [3]. The major advantages of cryopreservation are the lack of progressive loss of HCs over time and the greater flexibility in the timing of HCT relative to the collection of HCs, including the ability to modify or postpone a transplant conditioning regimen already started.

A progressive loss of HCs occurs during non-frozen storage. One author reported a 61% loss of myeloid colony-forming progenitor cells [colony-forming units – granulocyte macrophage (CFU-GMs)] from marrow after 72 hours of storage at 4 °C [4]. Yet another found only a 3% loss of CFU-GMs from BM stored for 96 hours, but a 95% loss if the source of the cells was peripheral blood [5]. As part of a clinical trial described later, Preti et al. compared the survival of mature hematopoietic progenitor cells isolated from marrow during frozen or non-frozen storage, and reported an immediate loss of myeloid (CFU-GM) progenitors of 33% during cryopreservation and thawing [6]. In contrast, cells stored at 4 °C showed a progressive, linear loss of total nucleated cells, cell viability, and HCs cloned in vitro. The quantity of erythroid colony-forming progenitor cells [burst-forming units – erythroid (BFU-Es)] in these non-frozen samples became significantly less than that of cryopreserved samples only after 5 days of storage. The difference for myeloid progenitor cells (CFU-GMs) was not yet significant even after 9 days of storage.

These differing reports demonstrate that storage conditions such as the concentration of cells, chemicals added, product volume, storage bag, and temperature of storage will affect the survival of cells kept in non-frozen storage. Most published reports of non-cryopreserved storage describe storage at 4 °C. This condition provides a stable temperature compared with storage at ambient temperatures, which can be quite variable (and which must be considered during the shipping of products). The optimum temperature is not known and will probably depend upon such concerns as the pre-storage processing, the quantity and concentration of mature blood cells, the acid buffering capacity of the solution, and the gas-diffusion capacity of the storage container. Beaujean et al., for example, reported a much lower pH for PBHC products stored overnight at room temperature compared with storage at 4 °C [3]. Although they did not find a difference in the recovery of progenitor cells in their experiments, this effect may be damaging to HCs in other circumstances. Antonenas et al. also reported a better survival of PBHCs stored at 2–8 °C but no effect of storage temperature on BM cells [7]. Yet another report describes better survival of HCs stored at 37 °C and at 25 °C compared with cells stored at 4 °C [8]. The conflicting reports about optimal storage temperatures are difficult to interpret. Storage conditions for non-frozen storage have not been tested in an engraftment model, so proper storage conditions are not adequately defined. For laboratories intending to store HCs for prolonged periods without freezing, rigorous validation of the storage conditions must be pursued and strictly controlled.

Table 42.1 Hematopoietic cell cryopreservation: basic technical considerations

Item	Principle	Example
Prefreeze processing	Reduction of mature blood cells that are poorly cryopreserved	Separation of buffy coat cells or light-density cells
Cryoprotectant	Protection of the cells from ice formation and dehydration. May be "colligative" or "polymeric" or a combination of both	Colligative: dimethylsulfoxide, glycerol Polymeric: hydroxyethyl starch
Plasma protein	Reduces cryopreservation injury	Autologous plasma or plasma protein concentrates
Solvent	Provides a suspension of cells and diluent for cryoprotectants	Saline solutions
Cooling	Cooling rates are dependent on the cell being frozen and the cryoprotectant used	Hematopoietic cells in dimethylsulfoxide are cooled at 1–3 °C/min
Storage	Storage temperature must protect from ice recrystallization and progressive cell damage	Nitrogen liquid or vapor-phase. Addition of polymeric cryoprotectant may allow storage at warmer temperatures

There is limited experience with the autologous transplantation of non-cryopreserved HCs [4,6,9–11]. HCs appear to maintain viability for several days after collection if carefully stored. Preti et al. compared, in a non-randomized retrospective analysis, the engraftment kinetics of 54 patients who received cryopreserved marrow cells with 45 patients who received refrigerated cells [6]. The refrigerated cells were stored for a median of 4 days (range 3–9 days). The cryopreserved cells were stored a median of 69 days (range 5–981 days) at −80 °C using a cryoprotectant mixture of dimethylsulfoxide (DMSO) and hydroxyethyl starch (HES). Almost all patients were conditioned with a regimen consisting of carmustine (BCNU), etoposide, and cyclophosphamide. This group found no significant difference in engraftment kinetics for these two groups, although a small difference of a few days would not have been detected with the limited numbers of patients in this study.

Cryopreservation theory

The chemistry and biology of mammalian cell cryopreservation

The recovery of viable mammalian cells after cryopreservation and thawing became possible with the discovery that glycerol could be used for the freezing of bovine sperm [12]. Subsequent experiments demonstrated that marrow cells frozen with glycerol could be used to reconstitute the marrow function of irradiated mice [13]. Considerable exploration of the cryobiology of various mammalian and non-mammalian cells ensued. These studies defined the mechanism of cell damage incurred during cryopreservation and techniques to moderate that damage. The current understanding of cryobiology contends that ice crystal formation during cooling is the primary cause of cell damage [14]. This damage can be classified into two categories. At rapid rates of cooling, intracellular ice crystals may form, resulting in *mechanical* disruption of the cell and immediate cell death. At slower rates of cooling, ice crystal formation preferentially occurs in the extracellular space, resulting in increasing osmolality as free water is incorporated into the growing ice crystals. This loss of free water results in the concentration of extracellular solutes such as sodium that do not freely penetrate the cell membrane, extreme hyperosmolality, and *dehydration* injury. For example, the molality of sodium chloride (NaCl) in a saline solution at −10 °C is about 5.3 *m*, and that at −20 °C about 10.5 *m*.

Intracellular ice formation may be limited by cooling cells slowly. At slow rates, it is probable that ice nucleation will occur first in the larger volume outside the cell. Progressive dehydration of the cell will result if the rate of cooling is slow enough to allow water to shift to the extracellular space and be incorporated into the growing ice crystals. The optimal cooling rate differs for different cell types and appears to be defined by the permeability of water through the cell membrane [15]. Progressive dehydration with concentration of intracellular solutes prevents the supercooling of intracellular water and protects the cells from the formation of intracellular ice crystals. Ice that happens by chance to nucleate first within a cell will result in the death of that cell, but will also serve to promote the freezing of extracellular water as the ice crystal penetrates the cell membrane. The corollary is not true in that extracellular ice does not penetrate into the cell and promote intracellular ice formation, presumably because of some feature of the cell membrane.

Glycerol and DMSO are colligative cryoprotectants that prevent dehydration injury by moderating the increased concentration of non-penetrating extracellular solutes during ice formation, and by decreasing the amount of water absorbed by (in equilibrium with) the ice crystals at a defined temperature. "Colligative" refers to properties dependent upon the number of particles (solute) and not the composition of the particles. Freezing is the crystallization of water, and the freezing point is the temperature at which ice crystals can be sustained in equilibrium with water. The freezing point of water is depressed by the addition of solute. For any particular mixture of solute(s) and water, there will be a defined temperature at which ice crystals can initially form. Unlike pure water, ice crystal formation and growth in aqueous solutions occurs over a temperature range. Growing ice crystals absorb free water and exclude solute particles. The incorporation of water into ice results in concentration of the solute and further depression of the freezing temperature of the remaining water, thereby preventing additional ice formation unless further cooling occurs. Thus, temperature (and pressure) defines the equilibrium between ice and the non-frozen solution. With further cooling, a temperature is eventually reached at which the solute itself crystallizes (eutectic point). The molality of a solution in equilibrium with ice is therefore determined by the temperature of the solution, not the initial concentration of the solute, as depicted by the equation

$$m \approx \frac{273 - T}{1.9}$$

in which m represents the osmolal concentration of the solute and T is the temperature in degrees Kelvin [16]. Similarly, the fraction of water not frozen (q) is defined by the equation

$$q \approx \frac{1.9Mo}{273 - T}$$

where Mo is the osmolal concentration of the solution before freezing.

In our example above, a saline solution at −20 °C has an NaCl molality of about 10.5 *m*. For a three-component system such as DMSO and NaCl in water, both solutes will contribute to the molality of the unfrozen solution in the same relative proportion found in the initial solution. The molality (before freezing) of 10% DMSO [volume in volume (v/v)] in normal saline (140 mM) solution is about 1.6 *m*, with DMSO contributing about 10 times the molality contributed by NaCl to the medium. At −20 °C, this molal ratio between DMSO and NaCl will be maintained. The molality contributed by NaCl will be about 1.05 *m*, or about seven times the molality of NaCl in a solution without ice. DMSO freely penetrates the HC cell membrane so that the intracellular concentration of DMSO will equal the extracellular concentration throughout the temperature range, assuming adequate movement of water from the cell as the extracellular ice crystals form and grow. The addition of a penetrating cryoprotectant to an aqueous saline solution therefore reduces the osmotic stress across the cell membrane at −20 °C from about 75 times to about seven times that of an ice-free solution. According to this theory, colligative cryoprotectants must be capable of penetrating the cell to avoid merely contributing to the molality of the extracellular medium, and must be non-toxic to the cells at the concentration required for this effect.

The tolerance of cells to freezing at slow cooling rates depends on the ability of the cells to withstand osmotic stress, and initial studies of the osmotic behavior of HCs have been reported [17]. The osmotic tolerance of granulocytes is much less than that for lymphocytes or CFU-GMs, probably accounting at least in part for the difference in survival after cryopreservation [18]. With DMSO concentrations of less than 10%, the degree of dehydration caused by concentration of the non-penetrating solutes during freezing will be greater because non-penetrating solutes will contribute proportionately more to the molality of the non-frozen solution in the extracellular medium. With higher concentrations of DMSO, the osmotic stress will be less. The optimal concentration for a colligative cryoprotectant depends upon the osmotic tolerance of the cell to be frozen, the toxicity to the cell of high concentrations of the cryoprotectant [19,20], and the presence of other cryoprotectants. The ability of a cryoprotectant to penetrate the cell and its subcellular organelles explains, at least in part, the relative efficacy of different colligative cryoprotectants for different cell species.

Colligative properties do not explain the cryoprotection achieved by freezing cells in solutions of macromolecules such as HES. Solutions of high molecular weight, polymeric cryoprotectants, contain relatively few particles and, moreover, do not freely penetrate the cell. These cryoprotectants may protect the cell by forming a viscous, non-crystalline, glassy shell that retards the movement of water, thereby preventing progressive dehydration as water is incorporated into the extracellular ice crystals [21]. Solutions of some compounds, when present in sufficiently high concentrations, will solidify to an amorphous glass without first forming ice crystals, a process termed vitrification [22]. The "glass-transition temperature" (T_g) depends upon both the structure and concentration of the solute. At very high concentrations of cryoprotectants (6.3 M for DMSO [22]), the T_g is higher (warmer) than the temperature at which ice crystals can form, thereby preventing crystallization during cooling and its resulting mechanical and osmotic stresses.

The practical difficulty with achieving vitrification arises from the necessity to use these very high concentrations of cryoprotectants. Vitrification has been used for the cryopreservation of murine embryos, for example, with a solution of 20% DMSO, 15.5% acetamide, 10% propylene glycol, and 6% polyethylene glycol [23]. Prolonged exposure to this solution was toxic, however, with complete loss of viability after 30 min at 4 °C. Kurata et al. plunged CBHCs protected by high concentrations of ethylene glycol directly into liquid nitrogen [24]. The recovery of HCs in samples preserved with the highest concentrations of ethylene glycol was similar to that for samples more conventionally cryopreserved with 10% DMSO (Table 42.2). The toxicity of the cryoprotectant solution was not addressed by these authors. Also, the rapid cooling and warming rates required are easier to achieve with the small cell aliquots (0.5 mL) tested than with the large volumes characteristic of HC products.

Table 42.2 Recoveries of nucleated cells and hematopoietic cells after cryopreservation with ethylene glycol or dimethylsulfoxide (DMSO)

Cryoprotectant solution	Cell recovery	CFU-GM recovery
8 M ethylene glycol	89.5 ± 8.5	66.6 ± 20.8
4 M ethylene glycol	83.6 ± 9.4	36.4 ± 23.6
2 M ethylene glycol	75.0 ± 17.4	14.7 ± 24.6
10% (v/v) DMSO	88.5 ± 12.4	69.1 ± 9.7

CFU-GM, colony-forming unit – granulocyte macrophage.

With lower concentrations of cryoprotectants, including extracellular macromolecular compounds and many sugars, crystallization occurs at warmer temperatures than the vitrification temperature and ice crystals will form during cooling. However, glass transition may occur even in the presence of ice crystallization. With the formation of ice crystals and resulting loss of free water, the concentration of the cryoprotectant in the non-frozen water will increase. With decreasing temperature causing increasing cryoprotectant concentration, a point will be reached at which the solution forms a glass. At this "limiting glass-transition temperature" (T'_g), the solution suddenly becomes viscous, retarding if not stopping the flow of water through the extracellular matrix. This has been proposed as the mechanism for cryoprotection afforded by the extracellular cryoprotectants [21]. In one study of peripheral blood monocyte cryopreservation using extracellular cryoprotectants, a limiting glass-transition temperature of −20 °C was optimal, which was achieved using a 20% solution of HES [21]. Substances forming glasses at higher or lower temperatures were less effective. Pure water forms a glass at about −139 °C [25]. The addition of cryoprotectants such as DMSO, glycerol or HES raises the T'_g [26]. This model of cryopreservation requires adequate dehydration to occur to concentrate intracellular solutes and decrease the probability of intracellular ice formation, but glass formation at an appropriate temperature (please recall that temperature defines the osmolality of the unfrozen aqueous solution) to prevent excessive dehydration of the cell.

Cells are not frozen in simple two- or three-component solutions but rather in complex solutions containing salts, sugars, penetrating cryoprotectants with or without extracellular cryoprotectants, and plasma proteins. Phase-transition temperatures (such as T'_g) for these solutions have not been published. The improved survival observed with increasing protein concentration [27], and, possibly, by combined penetrating and extracellular cryoprotectants [28], may be explained at least in part by these theories on ice and glass formation and their effects on the cell. Moreover, the existence of glass formation may explain the relationship between storage temperature and survival of HCs over time. Below the T'_g temperature, enlargement of previously formed ice crystals by recrystallization of unfrozen water cannot occur, and the cells are protected from progressive mechanical disruption. (The growth of an existing ice crystal through the process of recrystallization is thermodynamically more favorable than the nucleation of a new ice crystal.) The optimal storage temperature is below the T'_g for the cryoprotectant solution used. Warmer temperatures may be used, but at risk of cell damage, a risk that is dependent upon the temperature of storage and the stability (viscosity) of the solution at that temperature.

This simplified review of the effects of freezing and the cryoprotectant properties of penetrating and polymeric cryoprotectants does not completely explain the processes involved during freezing, and more detailed reviews of the freezing of aqueous solutions and mammalian cells have been published [29]. In addition to mechanical and dehydration injuries, cooling itself may be damaging to the cell [30]. Colligative effects alone are not sufficient to explain the cryoprotectant properties of DMSO or glycerol. Other freely penetrating chemicals such as urea and dimethylsulfone ($DMSO_2$) do not function as cryoprotectants for mammalian cells [31,32], and some chemicals such as ethanol and guanidine may actually function as cryosensitizers [33]. Obviously, the chemical structure of the cryoprotectant is important in the survival of mammalian cells, and a molecular interaction between the cryoprotectant and protein or lipid molecules appears necessary for optimal cryopreservation [34–37]. Examples of selective damage to cell membrane proteins or structure from freezing are illustrated by the loss of response to giant cell tumor-conditioned medium of myeloid progenitor cells after cryopreservation [38], the decrease in L-selectin expression by $CD34^+$ cells after cryopreservation and thawing [39], and the lineage-specific effects on granulocyte engraftment for patients receiving cells frozen with HES and DMSO in combination [40].

Induction of apoptosis during cell cooling

The recently demonstrated relationship of apoptosis with hypothermia may help explain HC losses during cooling and cryopreservation. Separate from cell necrosis resulting from the mechanical and dehydrating effects of cryopreservation, the induction of apoptotic pathways during cooling or after thawing may lead to further losses of HCs. Stroh et al. demonstrated caspase activation during the freeze–thaw process and reported improved survival of cells with the addition of a caspase inhibitor to the cryopreservation solution [41]. Benefit could be achieved also with the treatment of cells immediately after thawing, and the benefit was particularly significant for cells stored at warmer temperatures (e.g., –70 °C).

The physics of cooling and warming of cell products

The rationale for slow rates of cooling and rapid rates of warming is explained by the mechanical and dehydration injuries resulting from the formation and growth of ice crystals. Heat transfer is a physical process, not a biologic or chemical process. Cooling is a physical process dependent on properties of the object being cooled, such as the difference in temperature between the object and its environment, and the size and thermal conductivity of the object. The rate of heat transfer is described by the equation

$$q(r,t) = -k\nabla T(r,t)$$

in which $q(r,t)$ represents the heat-flux vector at a particular point on the object and a particular time, $-k$ represents the thermal conductivity of the material, and $\nabla T(r,t)$ represents the temperature gradient vector at that particular time and place. Objects with a greater thermal conductivity because of composition or smaller size will gain or lose heat more rapidly, as will objects placed in an environment with a much larger difference in temperature between the object and its environment.

Most centers use electronic rate-controllers to achieve an optimal cooling rate, but satisfactory rates of cooling can be achieved by simply immersing an appropriate volume of HCs into a –80 °C mechanical freezer [42–45]. Rowley cooled 50 mL aliquots in storage bags and found reproducible cooling rates of about 3 °C/min when placed in a –80 °C freezer, but rates between 10 °C/min and 16 °C/min when placed in a –135 °C freezer [42]. Clark et al. studied the effects of marrow volume on the cooling rates before and after the transition phase, and the duration of the transition phase for cells placed either in freezing bags or vials [45]. As would be predicted by the equation describing heat transfer, bags containing larger volumes cooled much more slowly and required longer duration of the transition phase (Table 42.3).

Table 42.3 Effect of product volume on cooling rate after immersion into a –70 °C freezer: rates of cooling before and after the transition phase, and the duration of the transition phase for samples of the stated volumes immersed into a 70 °C refrigerator

	Cooling velocity (°C/min)		Duration of transition phase (min)
Volume (mL)	Pre- transition	Post-transition	
30	6.1	2.0	0.5
60	3.1	1.6	3.0
90	1.6	1.0	8.6
120	1.8	1.0	12.8

Cryopreservation using an immersion technique is not “uncontrolled,” unless the physical parameters used are also not controlled, resulting in widely varying rates of cooling. Before immersion techniques are adopted by individual laboratories, the rate of cooling and reproducibility for the type of bag and volume of cells must be determined and documented. The advantages of immersion cooling techniques are the avoidance of a rate-controlled apparatus and the decrease in personnel time required. The disadvantages are the lack of a recording documenting the rate of cooling, the limited adaptability to different volumes and containers, and possible detrimental effects related to the duration of transition phase, which may be critical if borderline quantities of cells are harvested.

Cryoprotectant solutions

DMSO

DMSO, glycerol, and a variety of other chemicals may serve as colligative cryoprotectants that protect the cell from excessive dehydration as extracellular water is drawn into growing ice crystals. The cryoprotectant properties of glycerol were described in 1949 [12], and those of DMSO 10 years later [46]. The rapid diffusion of DMSO through the cell membrane, and the difficulty in removing glycerol before reinfusion (infusion of DMSO-containing products being generally tolerated), have made DMSO the favored agent for HC cryopreservation.

DMSO, a byproduct of paper manufacturing, is a hygroscopic polar compound developed originally as a solvent for chemicals such as insecticides, fungicides, and herbicides. Pure DMSO is a colorless, virtually odorless liquid (specific gravity 1.108, molecular weight 78.13 g/mol), although industrial grades may have a strong sulfur odor [47]. The serum half-life of DMSO is about 20 hours, although that of $DMSO_2$, a renally excreted metabolite, is 72 hours [47]. A small proportion of DMSO is reduced to dimethylsulfide, which is expired through the lungs for about 24 hours after administration, and which accounts for the characteristic odor resulting from DMSO infusion.

The optimal concentration of either DMSO or glycerol for the cryoprotection of HCs appears to be about 10%, although concentrations as low as 5% have been used successfully for HCT [48]. In their original report, Lovelock and Bishop demonstrated a dose–response with improving red cell survival as the concentration of DMSO was increased to 15% [46]. The effect of yet higher concentrations was not reported. Subsequently, Ragab et al. studied the survival of HCs from human donors after freezing with various concentrations of DMSO [27]. They found a significant increase in progenitor cell recovery when the concentration of DMSO was increased from 7.5% to 10%. No further improvement was found with an increase to 12.5%. This improvement resulted from an increase in nucleated cell recovery from 17.2% to 35.6% and 32.1%, respectively, after washing. Cell recovery before the post-thaw wash did not differ, nor did the numbers of colonies per 10^5 cells plated. The loss of cells during the wash steps that was found in this study may or may not reflect events occurring during direct intravenous infusion commonly used clinically.

Donaldson et al. studied the recovery of $CD34^+$ cells cryopreserved in varying concentrations of DMSO and HES and reported an increase in $CD34^+$ cell recovery from 12.2 ± 10.0% (mean ± standard deviation) to 85.4 ± 28.4% as the concentration of DMSO was increased from 2.5% to 5.0%, but no further improvement with further increase in concentration to 10% [HES concentration kept constant at 4% weight by volume (w/v)] [49]. Varying the concentration of HES in the presence of 5% (v/v) DMSO had no effect on $CD34^+$ cell recovery.

HES

HES is a polymeric substance containing chains of different molecular weights. Initially explored as a cryoprotectant for red blood cells, it was found also to be an effective cryoprotectant for a variety of other cells [21,50]. Macromolecular cryoprotectants may be used as single agents, but the major focus in the study of HC cryopreservation using extracellular cryoprotectants has been their use in combination with penetrating cryoprotectants. In one early study, the addition of polyvinylpyrrolidone, another macromolecular cryoprotectant, to glycerol or DMSO improved the cryopreservation of murine cells compared with the use of a penetrating agent alone [51]. Stiff et al. froze human cells in a combination of 5% DMSO, 6% HES, and 4% human serum albumin, and reported improved progenitor cell survival as determined using in vitro cultures [28]. They subsequently successfully used this mixture of cryoprotectants to cryopreserve the marrow of 60 patients [43]. No engraftment failure was attributed to this technique, or after the cryopreservation of peripheral blood-derived HCs [44]. A single-blind phase III study of 294 patients undergoing autologous PBHC transplantation using either DMSO alone or DMSO in combination with HES, found 1-day differences in the times to achieve a white blood cell count of 1 × 10^9/L and an absolute neutrophil count (ANC) of 0.5 × 10^9/L, and time to discontinuation of antibiotics for recipients of cells frozen with the combination cryoprotectant solution [40]. No differences were found for times to achieve endpoints of platelet engraftment, indicating that this effect was lineage specific. Furthermore, the effect was more pronounced for recipients who received more than the median number of $CD34^+$ cells, suggesting a specific effect on a limited cell population (Table 42.4).

Table 42.4 Engraftment kinetics of patients receiving peripheral blood hematopoietic cells frozen in dimethlysulfoxide (DMSO) or DMSO and hydroxyethyl starch (HES)

Outcome	**Patients below the median***			**Patients above the median***		
	DMSO	**DMSO/HES**	***p* value**	**DMSO**	**DMSO/HES**	***p* value**
Granulocyte engraftment						
WBC ≥ 1.0 ×10^9/L	11	11	0.71	11	10	0.02
ANC ≥ 0.1 × 10^9/L	10	10	0.86	10	9	0.03
ANC ≥ 0.5 × 10^9/L	11	11	0.87	11	10	0.01
ANC ≥ 1.0 × 10^9/L	13	12	0.87	12	11	0.02
Platelet engraftment						
Platelets ≥ 20 × 10^9/L	11	12	0.25	9	9	0.36
Platelets ≥ 50 × 10^9/L	14	15	0.10	12	12	0.28
Last transfusion	9	9	0.67	8	8	0.75

ANC, absolute neutrophil count; WBC, white blood cell count.
*Median times to achieve the designated outcome for patients classified by cryoprotectant used and stratified by quartile of $CD34^+$ cell dose/kg (first and second quartiles combined versus third and fourth quartiles combined). The median cell doses for patients receiving products frozen with DMSO alone was 6.4 × 10^6/kg, and for those receiving cells frozen with DMSO/HES was 6.5 × 10^6/kg. *p* values are based on weighted log rank test, which compares the two estimated recovery curves.

Protein

Plasma proteins exert cryoprotectant effects, possibly by modifying the viscosity or the glass-transition temperature of the cryoprotectant solution. Lymphocytes can be cryopreserved using serum alone [31,52]. The addition of serum proteins to the cryoprotectant solution appears to improve HC survival. In one study using human marrow cells, myeloid progenitor cell survival, which was 41.1 ± 8.0% in the absence of serum, increased significantly to 64.8 ± 14.2% with 15% serum and 75.4 ± 14.8% with 50% serum [27]. Similarly, recovery of murine spleen colony-forming cells (CFU-S) increased from 18.2% to 100.5% when frozen in 10% DMSO with 10% serum added [53]. In this second study, cryopreservation with 10% fetal bovine serum was less effective (25.4% recovery) than that with homologous serum, which may reflect the low protein content that is a characteristic of fetal sources of serum. The effect of protein content or source on engraftment speed has not been defined, but anecdotal experience would suggest that the presence of protein is important. Engraftment will occur for $CD34^+$ cells frozen without the addition of protein [54]. The 33 days (median) to achieve an ANC of over 500/μL and 46 days to achieve a platelet count of over 20,000/μL in the study that did not use protein in the cryoprotectant solution, however, were much slower than the 23 days and 22 days for ANC and platelet engraftment reported by Shpall et al. using a similar marrow-processing technique but different cryoprotectant solution containing protein [55].

Virtually all cryopreservation solutions currently in use contain plasma proteins added as either part of the cryopreservation solution or during cell processing. The range in concentration and source of protein varies among the various transplant groups; the source of protein is similarly diverse, although fetal bovine serum (used in some early trials of marrow transplantation) is no longer used. The use of albumin solutions is appealing because of the ability to achieve high, uniform concentrations of protein while avoiding the marrow fat, cellular debris, anticoagulants, and risk of cryoglobulins associated with the use of autologous plasma collected during initial processing of the HC product.

A unique group of proteins are the antifreeze glycoproteins found in some species adapted to survival in cold environments. Some of these proteins are extremely efficient at preventing the recrystallization of ice and have been shown to enhance the cryopreservation of pig and murine embryos [56]. In studies of red cell cryopreservation, this effect was limited to a narrow concentration range, with higher concentrations actually increasing the growth of extracellular ice, with concomitant cell damage [57]. It cannot be assumed that the addition of these proteins will improve HC cryopreservation survival.

Salt and sugar content

Metabolically inactive cryopreserved cells do not require the complex medium preparations used for ex vivo growth of HCs. Successful cryopreservation has been achieved using commercially available pharmacologic salt solutions. However, the solution in which the cells are suspended should not be viewed as inert. For example, many tissue culture media contain compounds that may increase the sensitivity of cells to freezing (cryosensitizers) [33]. Also, as noted in the second equation cited earlier, the fraction of unfrozen water is determined by the initial osmolality of the solution. At least for red cells, cryopreservation in hypotonic solutions increases post-thaw hemolysis [58].

Various sugars may function as cryoprotectants. Leibo et al. found 50% survival of CFU-S after cryopreservation of murine marrow cells in 0.35 M sucrose without protein or other cryoprotectants [59]. Optimal rates of cooling, as with other extracellular cryoprotectants, were between 16 and 70 °C/min. Cooling at slower rates (<10 °C/min) was associated with much poorer cryosurvival. Using a cell line derived from human kidney, Vos and Kaalen showed cryoprotectant properties for a number of sugars, including glucose, mannitol, and sorbitol, at concentrations greater than 0.1 M [31]. The amount of glucose in tissue culture media is in the millimolar range, which is negligible compared with the concentration shown by Vos and Kaalen to be an effective cryoprotectant in their system. These sugars do not freely penetrate the cell membrane, and function as extracellular cryoprotectants. Sugars may serve to stabilize the cell membrane during freezing or dehydration [35,36]. It has also been suggested that glucose may protect against the cytotoxicity observed with high concentrations of DMSO [60].

Cryopreservation technique

Evaluation of cryopreservation efficacy

A major impediment to the study of HC cryobiology is the inability to culture primitive HCs in vitro. The only "assay" for the cryosurvival of these cells is engraftment after transplantation, the rate of which depends more on patient diagnosis and marrow function, quantity of cells harvested, and any ex vivo treatment performed than on the cryosurvival of HCs as reflected by in vitro cultures [2]. Experimental models include engraftment of human cells in immunodeficient NOD/SCID mice [61]. Initial studies of blood and HC cryobiology used either metabolic assays or dye exclusion assays [62]. These assays are irrelevant, if only because the rarity of HCs in the HC product containing mostly mature blood cells precludes a correlation between cell metabolism or dye uptake and HC cryosurvival. Techniques that measure the viability of the whole population of cells are of no use in determining HC viability in that a complete kill of HCs would change the proportion of cells with vital dye uptake by less than 1%. HCs cannot be identified morphologically, and moreover, metabolic and dye exclusion tests do not measure the proliferative capacity of these cells (Table 42.5) [62].

Progenitor cell assays such as culture for CFU-GMs after thawing can be predictive of engraftment [1,2], but the validity of these assays must be determined for each group of patients and the assay used. DMSO must not be present in concentrations greater than 0.1% in in vitro cultures [63], so some technique of dilution must be undertaken before cell culture. Rapid dilution of DMSO after thawing exposes the cells to osmotic shock. Some authors have reported satisfactory recovery of HCs after rapid dilution of thawed cells [1,64]. Others, however, have demonstrated a distinct advantage to serial dilution [27,65]. Deoxyribonuclease (DNAse) can be added to lyse clumps that form. The addition of sorbitol or other macromolecular substances after thawing may be of value to help prevent osmotic shock [66,67]. These techniques, of course, differ from those of direct intravenous infusion.

Table 42.5 Protective effect of various additives for murine marrow cryopreservation: viability of bone marrow cells cryopreserved with various additives as shown by vital dye stains and the ability of these cells to rescue an animal from irradiation

Cryoprotectant	Viability by vital stain (%)	Animal survival (%)
Dimethylsulfoxide (15%)	91	70
Glycerol (15%)	75	70
Serum (30%)	90	0

Some centers routinely freeze "test vials" containing small aliquots of cells alongside the greater quantity of cells contained in freezing bags. The different cooling properties of vials compared with bags diminishes the reliability of these small aliquots for determining cryosurvival [45,68]. If an attempt is made to use small aliquots for clinical decisions, a system of cooling, thawing, washing, and culture that correlates with engraftment kinetics must first be developed.

Processing of HC products for cryopreservation

One of the basic concepts of clinical HC cryopreservation is the heterogeneity of BM and blood cell populations. HC cryopreservation involves the cryobiology of not only HCs, but also the mature blood cells contained in the harvested product. HCs comprise a very small portion (generally <1%) of the BMHC, PBHC, or CBHC. Cryopreservation techniques that are optimal for HCs will not preserve mature blood cells and the presence of mature blood cells affects HC cryopreservation in at least three ways. First, the large proportion of mature blood cells collected may hinder the laboratory processing if clumping before freezing or after thawing is induced by damaged granulocytes or platelets. Second, damaged cells may cause infusion-related toxicity. The infusion of marrow that was frozen without depletion of red blood cells was associated with acute renal failure in three of 33 patients in one study [69]. This problem presumably resulted from massive hemolysis of the poorly preserved red blood cells. Third, if the cells are frozen at a set concentration, the presence of large numbers of mature blood cells requires that the cells be frozen in large volumes. Patients receiving such products are at considerable risk for serious infusion-related toxicity from the large quantities of cryoprotectant used. In addition, the concentration of HCs before storage reduces the space required, a logistical consideration for the management of large banks of cells.

Therefore, cryopreservation of HCs can be facilitated by the prefreeze depletion of mature blood elements. A number of apheresis or cell-washing devices are capable of processing the large quantities of cells harvested. Some apheresis devices provide enrichment of mononuclear cells relative to granulocytes, providing a "cleaner" preparation for processing and cryopreservation. At the extreme of prefreeze processing is the extensive purification of HCs by isolation of $CD34^+$ cells, which reduces the quantity of mature blood cells and the amount of cryoprotectant infused, leading to a reduction in infusion-related toxicity. Collection of buffy coat cells with depletion of red blood cells is the minimum processing required for cryopreservation of marrow. PBHCs collected by apheresis contain small proportions of red cells and generally do not require further separation, although volume reduction will decrease the amount of cryoprotectant used. Cord blood cells are processed to reduce the storage volume required for the large banks of cells being stored. [67].

Cell concentration

The cell concentrations used in most protocols are often driven by such practical considerations as the desire to freeze more than one bag, or to minimize the total volume and number of bags of product stored. PBHCs differ from BM products because of their much larger nucleated cell quantity that must be processed by the laboratory. Although many protocols set limits for the concentration of nucleated cells, few also define the maximum or minimum concentrations or quantities of red cells, granulocytes, or platelets. The effect of these cells on HC cryopreservation is not defined, but a potential effect is illustrated by a report of poor post-thaw recovery of red blood cells frozen at high cell concentrations, which may relate to the limited space in channels of non-frozen water between the growing ice crystals during cooling and increased packing of cells [70].

Most studies involving cryopreservation of HCs at high cell concentrations were not designed to detect subtle damage from this practice. The cryopreservation of PBHCs at an average 3.7×10^8 nucleated cells/mL (range $0.4–8.0 \times 10^8$/mL) with no obvious correlation between cell concentration and engraftment kinetics has been reported [71]. Although there also was no correlation between cell concentration during freezing and the post-thaw recovery of $CD34^+$ cells, the recovery of CFU-GMs appeared to decrease at higher cell concentrations. Although cell cryopreservation at high concentrations of nucleated cells is feasible, Rowley et al. suggested that infusion of PBHCs frozen at high concentrations resulted in increased risk for neurologic events during or shortly after cell infusion [72].

The development of techniques that enrich for $CD34^+$ cells presents a different challenge to the cryopreservation laboratory. These techniques typically recover about 1% of the nucleated cells initially present. Cryopreservation of these cells in the same volume used for unselected cells would result in very low cell concentrations. Dicke et al. cite one study of murine marrow cryopreservation that showed stable CFU-S cryosurvival at cell concentrations between 5×10^6 and 2×10^8 cells/mL [65]. At cell concentrations of 1×10^6 cells/mL and below, however, CFU-S cryosurvival dropped precipitously. This decline may be related to non-specific losses such as adhesion to surfaces and post-thaw wash steps. $CD34^+$ cell-enriched products may be frozen in small vials or bags with adjustment of the cooling technique for the smaller volume.

Rates of cooling and warming

Different cells have different optimal cooling rates, and the optimal cooling rate is also dependent on the type and concentration of cryoprotectant used. In general, the higher the concentration of a colligative cryoprotectant, the slower the optimal cooling rate (Table 42.6). The optimal cooling rate when using a colligative cryoprotectant also falls within a narrow range. In contrast, optimal rates for cooling when using extracellular cryoprotectants are generally more rapid, and the cells tolerate a broader range (Table 42.6). Ma et al. used in vitro cultures of human bone marrow to show optimal cooling at 1 °C/min for human hematopoietic progenitor cells suspended in 10% DMSO [73]. The recovery of colony-forming cells fell at rates slower than 1 °C/min or faster than 3 °C/min. Lewis et al. studied the impact of cooling rates before and after the plateau phase (immediately after the "heat of fusion"), and of the duration of the plateau phase on the recovery of murine CFU-S frozen in 12% glycerol [74]. No difference was found for preplateau cooling rates ranging from 0.8 °C/min to 4 °C/min. Increasing the duration of the plateau phase from 0 to 16 minutes resulted in a drop in spleen colonies from 16.7 to 12.0. Increasing the rate of the post-plateau cooling similarly decreased CFU-S recovery. Clinically, Gorin et al. associated a rapid cooling rate with delayed engraftment for eight recipients of autologous marrow [75].

Table 42.6 Effect of cryoprotectant on optimal cooling rate for murine colony-forming units – spleen (CFU-S)

Cryoprotectant	Optimal cooling rate	CFU-S survival
0.4 M glycerol	100 °C/min	18%
0.8 M glycerol	18 °C/min	40%
1.25 M glycerol	1.8 °C/min	65%
0.35 M sucrose	16–70 °C/min	54%

Virtually all the reports regarding the optimal rate of cooling for HCs do not discuss the temperature at which time rate becomes irrelevant. This author has routinely increased the rate to 10 °C/min when the product reached −40 °C and transferred the bags to the storage refrigerators when a temperature of −80 °C has been reached [40]. At −40 °C, water will spontaneously nucleate so supercooled water cannot exist below this temperature [76]. Leibo et al. reported that most cell damage in their murine model occurred at temperatures between −10 °C and −45 °C [59]. Therefore, HCs may be tolerant of higher cooling rates after initial freezing of water.

The warming rate is more critical when rapid rates of cooling are used because of the intracellular ice nucleation that occurs with rapid cooling. If warming is slow during the thawing process, growth of these ice crystals by recrystallization can occur. Cooling at slow rates limits intracellular ice nucleation, and mechanical disruption of the cell from ice recrystallization during warming is less likely. Leibo et al. found no difference in CFU-S recovery for cells in 1.25 M glycerol cooled at 1.7 °C/min and warmed at either 1.8 °C/min or 910 °C/min [59]. Therefore, rapid warming is appropriate.

Storage of cryopreserved cells

Most laboratories store HCs below −120 °C in mechanical (electrical) refrigerators or in either the vapor or liquid phase of nitrogen. The rationale for this method is the possible progressive growth of ice crystals at warmer temperatures as water migrates from smaller to larger crystals (recrystallization), a process that does not occur in pure water at temperatures below about −130 ° to −139 °C [25,26], or in cryopreservation solutions cooled below the phase-transition temperatures of the mixture [25].

Critical phase-transition temperatures for HC cryoprotectant solutions containing DMSO or DMSO/HES have not been fully explored. Nor has the effect of storage or intermittent warming above these phase-transition temperatures on HC viability been determined. Initial attempts of autologous transplantation infused cells stored at −80 °C, although the mild, probably marrow-sparing, pretransplant conditioning regimens used in those initial trials hinder interpretation of the results [77]. In other, preclinical studies, however, progressive loss of HCs was demonstrated for cryopreserved cells stored at relatively warm temperatures. BM cells stored for 25 weeks in 10% DMSO at −30 °C failed to rescue mice from marrow-lethal irradiation, compared to 80% survival after 22 weeks storage at −70 °C and 72% survival after storage for 26 weeks in liquid nitrogen [78].

Illustrative of the need to maintain stable storage temperatures for long-term HC cryopreservation is the report by Appelbaum et al., using a dog model of autologous transplantation, of the failure of engraftment in 30%, 66%, and 100% of recipients of 0.5×10^8 marrow cells/kg stored in the vapor phase of nitrogen for 9, 12, and 18 months, respectively [79]. Storage at ultralow temperatures is not a requirement for successful engraftment if adequate numbers of HCs are harvested and if the duration of storage is limited. Under such conditions, moderate losses of HCs may occur without obvious delay in engraftment kinetics. The engraftment failure observed by Appelbaum et al. can be explained by their intentional cryopreservation and transplantation of borderline quantities of marrow cells and the probable instability of the storage temperature of their cells.

Nitrogen vapor-phase refrigerators are noted for the temperature gradient formed. Temperatures as warm as −100 °C may exist at the top of the refrigerator. Cells stored at this location will be exposed to additional warming upon opening of the refrigerator or lifting of the rack to gain access to the storage cassettes. Over a prolonged storage time, cells may be repetitively exposed to warming during normal operation of the refrigerator, and this warming may be progressively damaging to HCs. This temperature gradient in the vapor phase can be minimized by constructing frames from metals with better heat conductivity, such as aluminum. Rowley and Byrne found a gradient of only 5.9 °C at 22 inches (56 cm) above the liquid when using an aluminum racking system compared with a gradient of 86 °C for a similar refrigerator containing a racking system constructed of steel [80]. This design achieved stable low-temperature storage throughout the refrigerator.

In addition to the issue of temperature gradients in vapor-phase refrigerators, many laboratories perceive storage in the liquid phase to be safer because of the larger quantity of nitrogen present. However, liquid nitrogen can serve as a reservoir for viruses, which may be of clinical importance for high-potency pathogens that require only a few organisms contaminating the bag port for transmission of disease. This problem was dramatically illustrated by the transmission of hepatitis B infection to at least three patients whose cells were immersed in the same liquid nitrogen refrigerator as those of the index case [81]. Molecular typing of the virus and its isolation from the detritus of the refrigerator on subsequent investigation confirmed this mode of transmission.

It is possible that different cryoprotectant solutions may permit storage at warmer temperatures, although this has not been prospectively tested using appropriate models of engraftment. Many centers have adopted storage at −80 °C because of its simplicity for short-term storage for patients expected to undergo transplantation within a few weeks or months of cell harvest. Mostly, this storage is used in conjunction with DMSO/HES cryoprotection. Stiff reported successful transplantation of products stored for up to 22 months at this temperature [82]. Whether this accomplishment results from the addition of HES to the cryoprotectant solution, thereby affecting the stability of the solution at this relatively warm temperature, or because enough HCs were harvested to allow progressive loss was not analyzed. Galmes et al. reported a progressive loss of CFU-GMs and BFU-Es from PBHC products stored at −80 °C in either 5% or 10% DMSO (without HES) and recommended that duration of storage at this temperature be limited [83].

The duration of storage may be indefinite if adequate temperatures are maintained and appropriate cryopreservation techniques are used. Evidence supporting this premise is found in both laboratory and clinical experience. Parker et al. found no loss of colony-forming units culture (CFU-Cs) after storage of human marrow in vapor-phase nitrogen for a median of 42 months [84]. Cord blood stem cells maintain proliferative capacity and ability to engraft in a NOD/SCID murine model for at least 15 years [85]. Furthermore, limited numbers of patients have received HC products stored for prolonged periods of time. One report of experience from multiple centers reported transplantation of cells stored for up to 11 years [86]. In that study of 33 patients, however, the median duration of storage was only 2.8 years, the authors did not correlate duration of storage with engraftment kinetics or other markers of HC survival, and some products were treated ex vivo with mafosfamide, which is known to delay engraftment. Some patients experienced markedly prolonged post-transplant aplasia (up to 119 days), and two patients failed to engraft. Another study reported the outcome of transplantation for 36 patients who received marrow stored for 2–7.8 years, and found, in retrospective comparison to a control group who received cells stored for less than 2 years, no differences in success or speed of engraftment [87]. The products in that report were stored either in nitrogen vapor-phase refrigerators or mechanical freezers at −135 °C.

The temperature of storage should be maintained during transportation of marrow. The availability of "dry shippers" in which the nitrogen is absorbed into the wall of the container simplifies the transportation of frozen cells. These "shippers" can maintain nitrogen vapor-phase temperatures of about −180 °C for periods of 7–10 days (if stored upright). The amount of residual nitrogen at any time after filling is determined by weighing the container.

Cells may be stored either in bags or vials constructed of plastics tolerant to cryogenic temperatures. The advantage of vials relates to the ease with which samples may be thawed for analysis. The large numbers of vials required for storage, the risk of explosion on warming from nitrogen seepage into poorly sealed vials, and the higher risk of microbial contamination during handling are reasons that favor bags.

Post-thaw manipulation

DMSO and HES need not be removed before infusion if consideration is given to the potential toxicities of these agents. Most products may be frozen at sufficiently high cell concentrations that the total cryoprotectant dose is held within tolerable limits. Clumping of damaged cells may occur after thawing, especially if the cells are manipulated. For these reasons, most centers infuse cells within a few minutes after thawing and without any post-thaw processing other than filtration through a blood administration set.

Most DMSO-associated toxicities are related to the quantity of DMSO infused, which can be reduced by washing the cells after thawing. The techniques described generally involve serial dilution to avoid osmotic shock, and re-suspension in a protein-containing medium [88,89]. Beaujean et al. reported an average 73.9 ± 6.4% CFU-GM recovery (± standard error; range 20.5–158.2%) for 50 density-gradient separated marrows after thawing and washing [88]. The recovery for 12 peripheral blood products was 93.9 ± 7.0% (range 67.4–135.6%). Twelve of the marrow bags were stored at room temperature for 4 hours after washing, with an additional 20–25% loss of cells and CFU-GMs. These authors did not describe the speed of engraftment, compare engraftment kinetics to similar patients receiving unmanipulated cells, or correlate engraftment speed with either total cell or CFU-GM recoveries. There is no unequivocal evidence published to date that dilution of DMSO from HC products significantly affects engraftment kinetics.

The risk of post-thaw clumping can be diminished by removing granulocytes and platelets from the cell product before freezing, or by the addition of acid–citrate–dextrose (ACD). Symptomatic hypocalcemia occurs with the infusion of citrate anticoagulants, which may predispose the patient to adverse neurologic events during the infusion [72]. ACD will not lyse clumps that have already formed. Thawed cells should be infused through a standard blood administration set with an in-line filter of 170 μm pore size. It is possible to process HC products extensively after thawing, including the separation of CD34$^+$ cells from cryopreserved PBHC products [90]. Cell clumping during the processing is, as stated, a complication that appears related to the quantity of mature blood cells contained in the product.

Cryoprotectant toxicity

Toxicity to HCs

High concentrations of cryoprotectants may incur direct toxicity to the cells being cryopreserved (similar to the effects of vitrification solutions on murine embryos previously discussed). In general, cells are more tolerant to cryoprotectants at reduced temperatures. For example, DMSO is also concentrated during the formation of ice. Optimal cryopreservation requires a balance between protection from freeze damage and the occurrence of cryoprotectant-induced toxicity. Toxicity of DMSO to HCs has been described, and most laboratories minimize the time of exposure to DMSO of cells before and after cryopreservation. Using in vitro cultures, Douay et al. described a 23.5% recovery of CFU-Cs after 60 minutes' exposure (at 4 °C, without cryopreservation) and a 15% recovery after 120 minutes [91]. However, Rowley and Anderson were unable to confirm their findings of DMSO-induced progenitor cell loss in similar studies, and surmised that the difference between these reports might relate to the purity of the DMSO used [63]. In the latter study, which used pharmaceutical-grade DMSO, the recoveries of nucleated cells, CFU-GMs, and BFU-Es were virtually 100% after exposure to 10% DMSO at either 4 °C or 37 °C. Only at 20% concentration of DMSO did cell clumping cause a decrease in cell recovery to 21.7% (and total CFU-GM quantity to 27.1%). The numbers of myeloid and erythroid progenitors per 5×10^4 cells plated dropped only after exposure to 40% DMSO (3.3% of control after 60 minutes' incubation). Similarly, they found no loss of progenitor cells after thawing if the removal of DMSO was delayed even up to 60 minutes. Others have also reported no toxicity to HCs with short exposure to DMSO [73], although the direct addition of DMSO into the culture medium at 1% or greater concentration is toxic to cell culture [53].

Toxicity to the HCT recipient

In contrast, a high incidence of generally mild, infusion-related morbidity with the reinfusion of either marrow or PBHCs has been reported by several centers [91–94]. DMSO itself has a variety of pharmacologic effects, which may be compounded by the presence of lysed blood cells, foreign proteins from tumor-cell purging procedures or contaminants from non-pharmaceutical grades of reagents used in the processing. The LD_{50} values (amount of DMSO required to kill 50% of test animals) reported for intravenous infusion of DMSO are 3.1–9.2 g/kg for mice and 2.5 g/kg for dogs [47]. The acute toxic dose of DMSO for humans has not been determined. If a large amount of cryopreserved material is to be infused, the infusion can be separated over 2 days to avoid complications from the infusion of excessive amounts of DMSO.

The most dramatic toxicity is the rare anaphylactic reaction occurring during the initial administration of thawed cells. This appears to be an allergic reaction to DMSO, contaminants of DMSO (DMSO is a potent solvent, easily contaminated) or products of tissue culture medium once used for cryopreservation. Treatment of this complication is the same as for anaphylactic reactions to other medications and, after resuscitation of the recipient, the remainder of the cells may be administered cautiously. Non-allergic, profound hypotension may result from the intravenous infusion of DMSO, presumably from histamine-induced vasodilatation. Skin flushing, dyspnea, abdominal cramping, nausea, and diarrhea, reported to varying degrees after HC infusion, can also all be attributed to DMSO-induced histamine release. These complaints resolve over a few hours and are treated symptomatically.

DMSO has a variety of cardiovascular effects. In a series of 82 patients who were premedicated with diphenhydramine, Davis et al. observed increased blood pressure and decreased heart rate that were maximal about 1 hour after the completion of the marrow infusion [92]. A number of authors have noted cardiac arrest or high-degree heart block occurring during or immediately after the infusion of cryopreserved marrow or PBHCs [95–97]. In two series, the incidence of bradycardia (heart rate <60 beats/min) was 48.8% and 65%, that of second-degree heart block was 9.7% and 24%, and of complete (third-degree) heart block was 4.8% and 5.9% [96,97]. In both reports, the median time of onset was about 3 hours after the completion of the infusion. In one series, the authors noted that the heart block was often episodic, occurring with episodes of emesis [96]. In both series, the cardiac rhythm abnormalities resolved spontaneously within 24 hours of infusion. In contrast, Lopez-Jimenez et al. found no cardiac rhythm changes in a prospective series of 29 patients [98]. A break of 20 minutes was allowed between bags of thawed cells in this last series, and it may be the slower overall infusion rate that accounted for the lack of rhythm changes. Alessandrino et al. noted bradycardia for recipients of BM but not PBHCs, describing a higher risk of this complication for recipients of products containing higher quantities of red blood cells in the product [99].

Although headache in up to 70% of recipients of cryopreserved cells has been reported [94], other central nervous system complications are rare and generally related to the amount of DMSO infused. Two recipients who received HC products containing a total of 225 mL and 120 mL, respectively, of DMSO developed reversible encephalopathy [100]. The first patient underwent plasmapheresis, with a prompt improvement in mental status; the second patient recovered over 5 days without specific treatment. The weights of the patients were not cited in this report, but both patients probably received over 2 g DMSO/kg body weight.

In an attempt to reduce the volume of DMSO used during the cryopreservation of PBHCs, Rowley et al. concentrated cells to very high concentrations, averaging over 3.7×10^8 nucleated cells/mL [71]. They subsequently reported several patients who experienced seizures during the administration of these cells [72]. The average cell concentration for these patients was 6.9×10^8 nucleated cells/mL (range 0.8–12.9×10^8 cells/mL), but the maximum amount of DMSO administered was only 0.6 g/kg body weight. Administration of similar quantities of DMSO during the infusion of BM frozen at much lower cell concentrations has not been associated with seizures, so it is likely that these events are related to the cell concentration, cell quantity or types of cell cryopreserved in a

PBHC product. This laboratory previously added ACD (formula A) after thawing to prevent clumping. This practice was stopped after a high incidence of citrate toxicity, including occasional seizures, was observed.

Calmeis et al. reported a relationship between the quantity of non-HCs in the product and infusional adverse events for recipients of products from which DMSO had been removed before infusion [101]. Similarly, Milone et al. noted a correlation of infusion rate with cardiovascular changes, but a relationship between the non-mononuclear cells in the products and non-cardiovascular adverse events [102]. Marrows frozen in 10% DMSO (which itself is 1.4 *m*) have an average osmolality of 1794 mOsm/kg H_2O after thawing, and infusion through a central venous catheter is preferred. Painful irritation may occur if thawed cells are infused through a peripheral vein.

Despite the hyperosmolality of the products, serum osmolality is not greatly affected for patients receiving less than about 1 g DMSO/kg body weight**.** Davis et al. did not detect significant hemolysis in their clinical study, as reflected by a lack of major change in hematocrit [92]. Hemoglobinuria occurs frequently with BMHC infusions [94], presumably resulting from cryopreservation-induced hemolysis of red cells within the HC inoculum. In anticipation of the infusion of hemolyzed red blood cells, many centers manage patients with urinary alkylinization and mannitol diuresis using a strategy recommended for the treatment of acute hemolytic reaction to red cell infusion. This author discontinued this practice (but maintained prophylactic mediation with an antihistaminic agent and a corticosteroid) without an increase in postinfusion renal failure [40]. The infusion of large quantities of red blood cells in marrow products that were not red cell depleted before cryopreservation was associated with the development of acute renal failure in three of 33 patients at one transplant center [69].

In contrast to the extensive studies of DMSO-induced toxicity, little attention has been given to the toxicity of non-penetrating cryoprotectants. HES toxicity to HCs has not been reported. HES is widely used as a blood volume expander during surgery and to enhance the collection of granulocytes from healthy donors by apheresis methodology, and significant systemic toxicity from the infusion of HES is rare.

Special considerations

Cryopreservation of HCs intended for allogeneic transplantation

Cryopreserved HC products are not commonly used in allogeneic PBHC or BMHC transplantation. The availability of a volunteer donor at time of transplantation obviates the cost and risks inherent with the cryopreservation of cells. However, when concerns about the availability of the donor arise (e.g., foreign nationals, prisoners, substance abusers, or overly apprehensive donors), the collection and cryopreservation of cells before initiation of a myeloablative conditioning regimen may be justified. Obviously, the only practical method of storage of CBHCs involves cryopreservation, potentially for decades.

Limited experience in the allogeneic transplantation of cryopreserved marrow from related or unrelated donors has been published [103–106]. The probability and rate of engraftment were similar for recipients of cryopreserved cells and retrospective control groups of patients in the two studies that performed this analysis (Table 42.7). Long-term survival of these patients also appeared similar. Eckardt et al., however, described a significantly lower incidence of acute graft-versus-host disease (GVHD) for the recipients of cryopreserved cells [103]. Stockschlader et al. reported a similar study that found no difference in the incidence of either acute or chronic GVHD [104]. Both studies used total body irradiation or busulfan-based conditioning regimens, and cyclosporine and methotrexate for prophylaxis against GVHD for most patients. Stockschlader et al. subsequently published their experience with cryopreserved cells from unrelated donors (Table 42.7). The incidence of severe acute GVHD for recipients of cryopreserved marrow was 75% [106], which is similar to the reported experience of transplantation of non-cryopreserved cells from unrelated donors transplanted at a number of centers.

Table 42.7 Engraftment and outcome for transplantation of cryopreserved marrow from allogeneic donors

	Study 1		**Study 2**		**Study 3**
	Fresh	**Frozen**	**Fresh**	**Frozen**	**Frozen**
Number of patients	33	10	19	18	10
Days to absolute neutrophil count >500/μL	16	19	17	18	21
Days to platelet count >50,000/μL	28	23	ND	ND	ND
Acute GVHD ≥II	57.5%	20%*	64%	78%	6/8
Chronic GVHD	ND	ND	38%	55%	1/5
Day 100 mortality	39.4%	30%	32%	26%	4/9

GVHD, graft-versus-host disease; ND, no data.

Recipients of CBHCs experience slower engraftment compared with recipients of either marrow or PBHCs. It is likely that these observations result from the limited cell dose available in this source of HCs, and not from the cryopreservation process. The observation that granulocyte engraftment kinetics could be hastened by the post-thaw removal of DMSO for recipients of CBHC products could also be attributed to changes in the post-transplant immunosuppressive regimen (discontinuation of post-transplant methotrexate) or other modifications of the transplant regimen for the small number of patients reported [107].

Tumor cell purging

Some investigators have suggested that cryopreservation provides a purging mechanism that will reduce the risk of relapse after autologous HCT [108,109]. In one study, which used a rat model of acute myeloid leukemia (AML), Hagenbeek and Martens demonstrated a 30% recovery of normal CFU-Ss but only a 1.4% survival of splenic colonies derived from the leukemic cell line. Allieri et al. cloned leukemia progenitor cells (AML-CFUs) from the peripheral blood of five patients with AML before and after cryopreservation and compared the recovery of these cells with the recovery of CFU-GMs and BFU-Es from marrow specimens from healthy donors. The percentage recovery of AML-CFUs was always less than 50% of the percentage recovery of the normal cells in a series of cryopreservation experiments. Questions about the relevance of the models studied by these investigators can be raised, and whether cryopreservation of cells reduces the risk of relapse after autologous transplantation is not answered by these two studies. The demonstration using genetically marked cells that cryopreserved marrow products can be a source of relapse in patients treated for AML, neuroblastoma, and chronic myeloid leukemia suggest that cryopreservation is not a highly efficient purging technique [110–112].

Summary

The cryopreservation of HCs was explored from the earliest attempts to understand HCT. It should be obvious from this discussion that current cryopreservation techniques are satisfactory for the treatment of many patients, but no study has accurately quantified the HC losses resulting from cell freezing and the impact of these losses on engraftment kinetics after HCT. Virtually all centers freeze cells with DMSO alone or in combination with HES. The similarities between the techniques used by different transplant centers are much greater than the differences. Current cryopreservation techniques may reduce the HC content of the product, risking a potential delay in engraftment if inadequate quantities of HCs are harvested and stored. Moreover, there is considerable but generally minor toxicity from the currently used cryoprotectants, and the equipment and processing techniques are expensive.

The ideal cryopreservation solution is one that will achieve reproducible high cell recoveries, allow rapid cooling to minimize laboratory processing times, and be free of the toxicities associated with DMSO. More recent studies are focused on developing an understanding of apoptosis as a result of cell cooling, as opposed to cell necrosis from ice crystal formation, which may lead to modifications of cryopreservation solutions. These modifications, possibly the simple addition of inhibitors of apoptosis, may enhance engraftment kinetics with considerable savings in patient-care costs.

CHAPTER 43

Use of Recombinant Growth Factors after Hematopoietic Cell Transplantation

Jürgen Finke and Roland Mertelsmann

Department of Internal Medicine I, Hematology, Oncology and Stem Cell Transplantation, Freiburg University Medical Center, Freiburg, Germany

Introduction

The field of autologous and allogeneic hematopoietic cell transplantation (HCT) has changed considerably during the last decade due to the availability of growth factor mobilized peripheral blood hematopoietic cells as a graft source. Despite the more rapid hematopoietic reconstitution compared to the use of marrow-derived grafts, high-dose chemotherapy preceding HCT still induces a period of severe marrow aplasia with the risk of infections and bleeding, requiring prophylactic and therapeutic interventions. Sepsis during the time of neutropenia represents a major problem and may result in transplant-related death.

Hematopoietic growth factors and other cytokines contribute to the regulation of cellular growth and differentiation of the lympho-hematopoietic system. Early-acting growth factors contribute to the differentiation of pluripotent stem cells, capable of self-renewal, into multipotent and committed progenitor cells. Late-acting growth factors lead to further differentiation, eventually giving rise to mature cell elements with distinct function. However, almost all growth factors have multiple biologic activities, partly overlapping or synergistic with other hematopoietic growth factors, and can act on more than one cell type (Table 43.1). It has been demonstrated in murine models that in addition to very primitive long-term hematopoietic cells, other progenitor cells with a lower proliferative potential and restricted differentiation capabilities contribute to the hematopoietic reconstitution after HCT [1,2,3]. Kinetic as well as cell purification studies suggest that hematopoietic reconstitution in humans is dominated by different types of short- and long-term repopulating cells after HCT [4,5]. Myeloid-restricted short-term repopulating cells play a major role during the first few months after transplantation and are followed by a second type of long-term repopulating cells able to regenerate myeloid as well as lymphoid lineages [6].

After the discovery and clinical development of hematopoietic growth factor, for example G-CSF between 1984 and 1991 [7], the clinical impact on regeneration of hematopoiesis after chemotherapy has been extensively studied, demonstrating that engraftment kinetics after HCT can be influenced by the use of recombinant hematopoietic growth factors. Numerous studies, including randomized trials, have established the clinical role of specific growth factors after HCT. In the setting of allogeneic transplantation, not only the regeneration of the hematopoietic system but also the restoration of the immune system and modulation of GVHD continue to be of the utmost importance.

Erythropoietin

Erythropoietin (EPO) was the first growth factor to be identified experimentally and to be made available as a recombinant protein. EPO is widely used for the successful treatment of anemia associated with renal failure. The anemia encountered in HCT recipients is partly due to relative erythropoietin deficiency. Frequently, patients are already anemic prior to transplantation and present with elevated serum EPO levels [8]. Inappropriately low EPO levels in relation to the severity of anemia during the period following HCT is attributed to causes such as toxic effects of high-dose therapy and drugs like cyclosporine on EPO-producing cells of the kidney, as well as inhibitory effects of inflammatory cytokines like tumor necrosis factor-alpha (TNF-α) on hypoxia-induced EPO production.

Recombinant human EPO after autologous HCT

Several trials have addressed the value of recombinant human (rHu) EPO after transplantation to accelerate red cell regeneration and to decrease the need for red blood cell (RBC) transfusions. After autologous bone marrow transplantation (BMT), EPO has been used in phase II as well randomized phase III trials alone or in combination with granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF) [9,10]. Although EPO was tolerated without side effects and an increase in reticulocyte counts was attained, no obvious benefit regarding transfusional requirements, engraftment or treatment outcome was observed.

In a small case series of 28 patients with religous objection to blood products a combination of EPO, G-CSF, intravenous iron, and epsilon aminocaproic acid was given after autologous peripheral blood hematopoietic cell transplantation (PBHCT). With two treatment-related deaths (8%) and four bleeding complications the median fall of hemoglobin level was 4.7 g/% and the median total number of days with platelet count <10,000/μL was 4 days. This approach was judged to be safe without the use of any blood products post autologous PBHCT [11].

rHuEPO after allogeneic HCT

After allogeneic marrow transplantation EPO enhanced reticulocytosis, increased hemoglobin levels and reduced time to transfusion independence, resulting in the need for fewer RBC transfusions.

Table 43.1 Growth factors available for clinical use

Growth factor	Gene localization	Naturally induced by	Main effector lineage	Generic name
Erythropoietin	7q21	Hypoxia	Erythroid	Epoetin-alpha, -beta, darbepoetin-alpha
G-CSF	17q11.2–q12	IL-1, TNF-α, endotoxin	Myeloid	Filgrastim, pegfilgrastim, lenograstim, biosimilars
GM-CSF	5q31.1	TNF-α, lipopolysaccharide	Myeloid/macrophage	Molgramostin, sargramostim
IL-3	5q31.1	Activation	Progenitor/myeloid/lymphoid	–
SCF	12q22–24	Constitutive	Myeloid/lymphoid	Ancestim
MGDF/TPO	3q2–28	Constitutive (thrombocytopenia)	Megakaryocytic/progenitor	–
IL-11	19q13.3–13.4	IL-1	Lymphoid/myeloid/megakaryocytic	Oprelvekin
IL-2	4q26–28	Activated T lymphocytes	T/NK/B lymphocytes	Aldesleukin
KGF	15q15–21.1	Tissue damage, PDGF, TGF	Epithelial cells	Palifermin

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukin; KGF, keratinocyte growth factor; MGDF, megakaryocyte growth and differentiation factor; PDGF, platelet-derived growth factor; SCF, stem cell factor; TGF, transforming growth factor; TNF-α, tumor necrosis factor alpha; TPO, thrombopoietin.

In a large multicenter, placebo-controlled, randomized trial, 106 patients were treated with EPO after allogeneic BMT and 109 patients with placebo [12]. Patients received either 150 IU/kg/day EPO or placebo as continuous intravenous (IV) infusion. Therapy started after BMT and was continued until independence from RBC transfusions for 7 consecutive days with stable hemoglobin levels greater or equal to 90 g/L or until day 41 after BMT. The reticulocyte counts were significantly higher with EPO from day 21 to day 42 after BMT. The median time to RBC transfusion independence was 19 days (range, 16.3 to 21.6) with EPO and 27 days (range, 22.3 to >42) with placebo ($p < 0.003$). A multivariate analysis showed that acute GVHD, major ABO blood group incompatibility, age above 35 years, and hemorrhage significantly increased the need for transfusions. After day 20, EPO significantly reduced the number of RBC transfusions in these patient groups [12].

In another phase III trial in allogeneic BMT, 50 patients were randomized to treatment with EPO ($n = 25$) or placebo ($n = 25$) [8]. EPO was given at 200 U/kg daily for 4 weeks and 200 U/kg twice weekly for a further 4 weeks. There were no differences between the two groups regarding time to engraftment, fever, hospitalization, GVHD, infections, hemorrhages, transplant-related mortality, relapse, and survival. However, more patients in the control group had an elevated serum creatinine (43% vs. 14%; $p = 0.04$). RBC transfusion requirements for the first 2 months after BMT were significantly lower in the EPO group compared with the control group (5 units vs. 10; $p = 0.04$). Time to unsupported Hb >70 g/L was shorter in patients treated with EPO (14 days vs. 24; $p = 0.03$). No effect was seen on platelet engraftment or the number of transfused platelet units [8].

Ninety-one patients between the ages of 17 and 58 years undergoing allogeneic transplants from sibling donors were entered into a double-blind randomized trial to evaluate the effect of EPO at a dose of 300 U/kg/day given thrice weekly by intravenous injection. Treatment ended when the hemoglobin exceeded 120 g/L and recommenced if hemoglobin fell below 120 g/L, at 150 U/kg/day. Patients received two units of erythrocytes when hemoglobin dropped below 85 g/L. In a multivariate analysis, the administration of EPO was associated with an 18% reduction in RBC transfusion requirement when other variables were taken into account [13].

Allogeneic HCT with major ABO blood group incompatibility may be associated with a markedly prolonged time to red blood cell engraftment, immune hemolysis or pure red cell aplasia. Reports suggested a curative effect of EPO for these patients [14,15]. A 32-year-old AML patient developed pure red cell aplasia after major ABO-incompatible BMT. After receiving rHuEPO and methylprednisolone she developed reticulocytosis and hemolysis. She promptly recovered from hemolysis and pure red cell aplasia after plasmapheresis [15]. In the era of reduced-intensity conditioning using fludarabine-based conditioning regimens, a higher incidence of pure red cell aplasia may be expected in patients with high antidonor isoagglutinins in comparison to myeloablative regimens [16].

The role of EPO was also examined in the context of RIC. A phase II trial addressed the role of EPO given either from day 0 (19 patients), or starting day 28 (27 patients) after reduced-intensity conditioning and allogeneic HCT. EPO was administered subcutaneously once weekly at a dose of 500 U/kg/week and 14 patients receiving no EPO served as control group. Up to 6 months post-transplant, Hb values were significantly higher in patients receiving EPO compared to those receiving no EPO, but transfusion requirements were decreased only in the first month in patients receiving EPO from day 0. Interestingly, a reduced T-cell chimerism below 60% negatively influenced Hb levels post-transplant [17].The frequency of and risk factors for persistent anemia and inadequate EPO secretion were investigated after allogeneic stem cell transplantation (SCT) [18]. Of 83 evaluable allo-HCT patients, 63 (76%) developed persistent anemia at a median of 34 (range: 30–244) days after allo-SCT. Forty-one (49%) patients had anemia considered as primary, and in all of them inadequate serum EPO levels (median 43.3, range: 2.5–134 mU/mL) were found. A high creatinine level during the first month after allo-HCT was associated with primary anemia [relative risk (RR) 2.5; $p = 0.01$]. Of the 41 patients, 35 received erythropoiesis-stimulating proteins (ESP). Transfusion independence and an Hb level higher than 10 g/dL was achieved in 29 of 30 (97%) evaluable patients.

Summary: clinical use of EPO after HCT

In summary, EPO stimulates erythroid engraftment after BMT resulting in a small but significant reduction of RBC transfusion requirements. Whereas trials after autologous transplantation showed marginal benefits, the beneficial effect after allogeneic HCT was more prominent. Anemia associated with impaired EPO secretion after allo-SCT is more frequent than generally recognized and it is associated with early post-transplantation renal damage. Late after allogeneic HCT individual patients with delayed or inadequate erythropoiesis with inappropriate reticulocyte counts and inadequately low serum EPO levels, for example in patients with renal impairment, chronic inflammation, or chronic GVHD, are likely to benefit from the application of EPO.

Granulocyte colony-stimulating factor

Granulocyte colony-stimulating factor (G-CSF) is produced by many cell types and is rapidly induced by inflammatory stimuli. In vivo studies demonstrated that G-CSF is a potent myeloid growth and differentiation factor. The dose-dependent increase of peripheral blood neutrophils is caused by expansion of the myeloid compartment in the marrow, an accelerated production of mature neutrophils and a rapid shift of mature neutrophils from the marrow sinusoids into the peripheral blood [7].

Side effects of rHuG-CSF administration are usually mild and include bone pain, occasionally low grade fever, and weight gain. After high-dose therapy and HCT, transient pulmonary infiltrates that cause dyspnea, especially during the early phase of hematopoietic engraftment, can occasionally be observed radiologically and clinically. High-dose corticosteroids and diuretics are the treatment of choice for this complication. The entity of the clinical findings of fever, capillary leak, and pulmonary infiltrates, frequently also including a skin rash, observed during engraftment after HCT, has been termed "engraftment syndrome" and post-transplant G-CSF increased the incidence of this syndrome [19].

Two recombinant preparations of G-CSF are commonly in use, filgrastim produced in *E. coli* and the glycosylated form, lenograstim, produced in a Chinese hamster ovary cell line. More recently, also various biosimilar generic G-CSF products have attained clinical approval. The difference between the various G-CSF products appears to be minor. Filgrastim is also available in a pegylated formula, pegfilgrastim, for single-dose use.. The term "G-CSF" is generally used for the various recombinant products, unless the pegylated variant is specified.

G-CSF after autologous HCT

G-CSF after autologous BMT

Early data suggested that, after autologous BMT, neutrophil recovery was accelerated in G-CSF-treated patients compared to historical controls. Neutrophil counts exceeded 0.5×10^9/L on the G-CSF arm at a mean of 11 days after marrow infusion compared with 20 days for controls, a significant difference. This reduction led to significantly fewer days of parenteral antibiotic therapy, 11 versus 18 days in controls, and less protective isolation in reverse-barrier nursing, 10 versus 18 days [20]. Similar data were obtained after autologous BMT in lymphoma patients [21].

Several large randomized trials have confirmed the significantly accelerated neutrophil engraftment after autologous BMT compared to placebo (Table 43.2). In the first, G-CSF was given to 315 patients after autologous or allogeneic BMT in a prospective randomized placebo-controlled multicenter trial [22]. One day after bone marrow infusion, 163 patients received lenograstim 5 μg/kg/day by 30-min infusion, and 152 patients received placebo daily for 28 days or until neutrophil recovery. Neutrophil recovery to above 10^9/L for 3 consecutive days was seen earlier in G-CSF-treated patients (16 vs. 27 days; $p < 0.001$). Time to neutrophil recovery above 0.5×10^9/L was reduced (14 vs. 20 days; $p < 0.001$). The difference was significant both in autograft (20 vs. 14 days; $p < 0.001$) and in allograft (20 vs. 14 days; $p < 0.01$) patients, in children (20 vs. 13 days; $p < 0.001$), and in adults. G-CSF-treated patients had fewer days of infection, of antibiotic administration, and also spent less time in hospital. However, the incidence of clinical and microbiologic sepsis was similar in both groups. There was no significant toxicity ascribed to G-CSF. Survival was similar between groups at both days, 100 and 365, after transplantation [22].

Table 43.2 Randomized placebo controlled trials of G-CSF following HCT

Number of patients enrolled	Type of transplant	G-CSF given from day	ANC >500/μl (day after transplantation)		*p* value	Reference/ Comment
			G-CSF	Placebo		
315	Auto/Allo BMT	+1	14	20	0.001	[22] Placebo controlled
43	Auto BMT	+1	10	18	0.0001	[23] Placebo controlled

Auto, autologous; Allo, allogeneic.

Patients with lymphoma were treated in a randomized, open-label trial to study the use of G-CSF as an adjunct to high-dose chemotherapy and autologous BMT [23]. Of 43 patients, 19 were randomized to receive filgrastim by continuous subcutaneous infusion at a dose of 10 μg/kg/day, 10 to filgrastim 20 μg/kg/day, and 14 to a parallel control group that received no filgrastim. The median time to neutrophil recovery greater or equal to 0.5×10^9/L after the day of autologous BMT was significantly accelerated to 10 days in the combined G-CSF groups compared with 18 days in control patients. The median number of platelet transfusions was identical in both groups. Clinical parameters, including the median number of days with fever (1 vs. 4) and neutropenic fever (5 vs. 13.5) were significantly improved in the G-CSF group compared to the control group. For patients treated with the two different dose levels of G-CSF, the neutrophil recovery and clinical results were similar [23].

Forty-one patients undergoing high-dose therapy followed by infusion of autologous PBHCT with or without bone marrow were randomized to receive G-CSF 5 μg/kg/day beginning on day + 1, or no G-CSF. [24]. The median time to a neutrophil count greater or equal to 500/μL was significantly shorter with 10.5 days in the G-CSF group compared to 16 days in the control group. G-CSF was associated with statistically significant reductions in the time to neutrophil engraftment among patients who received PBHC alone (11 vs. 17 days) and in patients who received PBHC in conjunction with bone marrow (10 vs. 14 days) [24].

In 54 patients with malignant lymphoma, hematopoietic recovery after high-dose chemotherapy and autologous BMT was compared between patients randomized to receive 10 or 30 μg/kg/day of filgrastim or no growth factor [25]. After high-dose chemotherapy with cyclophosphamide, VP-16, BCNU (CVB) or a BCNU, etoposide, cytosine arabinoside, melphalan (BEAM) regimen followed by autologous BMT, filgrastim was administered by continuous intravenous infusion from the first day after autologous BMT until neutrophil recovery. When the filgrastim groups were compared with the control group the major findings were: the median time to reach an ANC greater or equal 0.5×10^9/L was 20 days in the control group and 12 and 14 days, respectively, in the filgrastim groups ($p = 0.0004$). The duration of neutropenia (ANC $< 0.5 \times 10^9$/L) was reduced from

27 days in the control group to 11 and 13 days in the G-CSF groups ($p = 0.0001$). In addition, fewer days of febrile neutropenia were observed in the G-CSF groups (5 and 6 days) than in the control group (10 days; $p = 0.036$). No significant effects on the total number of days with fever were observed [25]. An accelerated neutrophil engraftment was also observed in 41 consecutive children undergoing autologous BMT for hematologic malignancies in comparison with a similar historical control group of 38 children who did not receive G-CSF after autologous BMT. Their ages ranged from 2 to 16 years (mean 7.2 years). G-CSF was given at a dose of 10 μg/kg/day IV in a 2-h infusion from day +1 until +28 or until the ANC was $>1 \times 10^9$/L [26].

G-CSF after autologous PBHCT

The results obtained after autologous BMT were essentially confirmed in several phase II and III trials (Table 43.2) addressing the role of G-CSF after myeloablative chemotherapy and autologous cytokine mobilized PBHCT [27–30]. Of note, since engraftment after PBHCT is generally accelerated compared to unstimulated BMT, the potential benefit of G-CSF given post PBHCT is likely to be smaller.

Thirty-eight patients with lymphoproliferative disorders were randomized to receive low-dose filgrastim (19 patients) or placebo (19 patients) beginning on the first day after HCT [27]. All patients received more than 2.5×10^6 CD34$^+$ cells/kg, which had been mobilized with chemotherapy and filgrastim 300 μg from day 5. Neutrophil engraftment was significantly more rapid in patients who received G-CSF, with a median number of days until ANC greater than 0.5×10^9/L of 10 (9 to 13) versus 14 (9 to 19). The time to reach an ANC greater than 1×10^9/L was 12 (9 to 14) versus 16 days (10 to 25). The total number of patients who required intravenous antibiotic therapy was lower in the G-CSF-treated group (68%) compared with the placebo group (89%) [27].

In another prospective study, 34 patients had been randomized to receive lenograstim and 28 to no growth factor [28]. The median time to ANC $>0.5 \times 10^9$/L was 9 days in the G-CSF arm versus 12.5 days in the no-G-CSF arm ($p = 0.0001$). Median days to platelet independence, platelet transfusions, incidence of infection, and RBC transfusion were the same in both arms [28].

Factors influencing hematopoietic engraftment were analyzed within the French multicenter LNH93-3 trial treating patients with aggressive high-grade NHL with intensive chemotherapy including BEAM and autologous PBHCT [29]. In the patient population treated with the same first-line regimen, bone marrow involvement and infusion of fewer CD34+ cells delayed platelet recovery. Administration of G-CSF after PBHCT significantly reduced neutropenia [29].

The effect on accelerated neutrophil engraftment by G-CSF appears to be preserved when the start of application is delayed to day +5 after HCT. Sixty-two adult patients were randomized to receive filgrastim after PBSC infusion ($n = 30$) and 32 patients, the control group, received no cytokines [30]. G-CSF was administered subcutaneously from day +5 in the treated group at a dose of 5 μg/kg body weight/day. Faster granulocyte engraftment was evident in the treated group (mean of 10 vs. 12 days to achieve $>0.5 \times 10^9$/L granulocytes; $p = 0.0008$), without differences in incidence and severity of infections, days of fever, or duration of antibiotic treatment between groups.

Several randomized trials showed no delayed neutrophil engraftment when G-CSF was not given before days +3, +5, +6, or +7 after PBHCT [31–33]. Early (day +1) or delayed (day +7) G-CSF after immunoselected CD34+ autologous PBHCT significantly accelerated ANC recovery but did not reduce the amount of supportive treatment or the duration of hospitalization in 21 consecutive patients with hematologic malignancies [34].

A randomized trial compared pegfilgrastim with filgrastim after high-dose melphalan and autologous PBHCT in 37 multiple myeloma patients receiving a single 6 mg dose of pegfilgrastim on day 1 post-transplant versus daily subcutaneous injections of filgrastim 5 μg/kg starting on day 5 post-transplant. The median duration of grade 4 neutropenia in the pegfilgrastim and filgrastim groups was 5 and 6 days, respectively (p = not significant). The results for the two groups were also not significantly different for time to neutrophil and platelet recovery, but incidence of febrile neutropenia (61.1% vs. 100%; $p = 0.003$) and duration of febrile neutropenia (1.5 vs. 4 days; $p = 0.005$), were lower in the pegfilgrastim arm demonstrating the safety and efficacy of this approach [35].

A single dose of 6 mg of PEG-filgrastim on day +5 was compared to G-CSF, given from day +2 until neutrophil recovery following high-dose melphalan and PBHCT for patients with multiple myeloma (MM) in an outpatient setting [36]. Overall, a second hospital admission was required in 36 procedures out of 161 (32%). Febrile neutropenia (FN) and severe mucositis were the most frequent causes of hospitalization. In the PEG group, readmission was needed in 6 out of 48 autografts (12%) as opposed to 30 out of 113 (26%) in the G-CSF subgroup ($p = 0.06$). The median time of hospital stay for readmitted patients was identical for the two subgroups (9 vs. 9 days; $p = 0.94$). One case of transplant-related mortality occurred in the whole patient series (0.6%). The authors concluded that autologous HCT on an outpatient basis is feasible and safe in patients with MM, the majority of whom are manageable at home. The administration of a single-dose PEG-filgrastim resulted in no different outcome in terms of safety and efficacy as compared to 8 days of G-CSF.

In a phase II study in patients receiving autologous HCT for MM and lymphoma 40 patients received pegfilgrastim 6 mg on day +1 and 40 were treated with daily filgrastim starting at median day +7 (5–7). Duration of neutropenia, intravenous antibiotic use, and hospitalization favored pegfilgrastim, while platelet engraftment, transfusion requirement, and fever duration were equivalent in both groups [37].

In a randomized study, 101 patients who were eligible for PBHCT and aged >18 years were identified before high-dose chemotherapy, after the harvesting and cryopreservation of peripheral blood progenitor cells [38] (Table 43.3). Eligible patients received either standard carmustine/etoposide/cytarabine/melphalan (BEAM) or carmustine/etoposide/cytarabine/cyclophosphamide (BEAC) high-dose chemotherapy. Before high-dose chemotherapy, patients were randomly assigned to receive pegfilgrastim 6 mg on day 1, or weight-based dose-adjusted filgrastim beginning on day 1 after transplantation until neutrophil engraftment. In this randomized trial, pegfilgrastim appeared equivalent to multiple daily doses of filgrastim [38].

In a double-blinded, placebo-controlled trial compared the efficacy, costs, and safety of single-dose pegfilgrastim (single 6 mg dose) versus daily filgrastim (5 μg/kg/day) 78 patients were enrolled [39]. Cytokines were started on day +1 post-transplant and continued to an absolute neutrophil count (ANC) of 5×10^9/L for 3 days or 10×10^9/L for 1 day. The median time to neutrophil engraftment (ANC $>1.5 \times 10^9$/L for 3 days or 5×10^9/L for 1 day) was the same in both groups (12 days). No differences in platelet engraftment (11 vs. 13 days), number of platelet transfusions (5 vs. 4), percent with positive cultures for bacterial pathogens (23% vs. 15%), days of

Table 43.3 Randomized trials of pegfilgrastim versus filgrastim following HCT

Number of patients enrolled	Type of transplant	CSF given from day	ANC >500/μL (day after transplantation)		*p* value	Reference
			Pegfilgrastim	Filgrastim		
78	Auto PBHCT	+1	12	12	n.s.	[39]
80	Auto PBHCT	+1	10.8	11.5	n.s.	[98]
151	Auto PBHCT	+5	FN 3.07	FN 3.29	n.s.	[99]
101	Auto PBHCT	+1	9.3	9.8	n.s.	[38]

Auto, autologous; FN, febrile neutropenia; n.s., not significant.

fever (1 vs. 2), deaths prior to engraftment (1 vs. 1), or duration of hospital stay (19 vs. 19 days) were seen between the pegfilgrastim and filgrastim groups, respectively, demonstrating the clinical equivalence of pegfilgrastim and filgrastim when given post-autologous PBHCT [39].

To address the question of the optimal application time 53 patients were randomly assigned to pegfilgrastim on day + 1 or day + 4 after autologous HCT [40]. Median time to neutrophil and platelet recovery was 10 days in both treatment arms and there was no difference regarding the incidence (67% vs. 60%; $p = 0.77$) or duration of febrile neutropenia episodes in both groups.

G-CSF after allogeneic HCT

Initial concerns over potential aggravation of GVHD or an increase of relapse in patients with myeloid leukemias tempered the use of growth factors after allogeneic BMT. Essentially, after allogeneic BMT the same effects as after autologous transplantation can be observed. Schriber et al. reported the experience with 50 patients treated at a single institution using G-CSF after allogeneic sibling ($n = 30$) and matched unrelated ($n = 20$) BMT [41]. The time to an ANC greater or equal 500/μL was significantly faster in patients who received G-CSF and cyclosporine and prednisone for GVHD prophylaxis when compared to historical control patients receiving the same GVHD prophylaxis without G-CSF (10 vs. 13 days; $p < 0.01$). A similar accelerated myeloid engraftment was observed for patients who received additional methotrexate for GVHD prophylaxis when compared to historical control patients receiving the same GVHD prophylaxis regimen (16 vs. 19 days; $p < 0.05$) [41]. Similar results were obtained in children [42].

Delayed treatment with G-CSF resulted in a reduction of G-CSF treatment from 19 days to 14 days ($p = 0.0017$) in 38 patients randomly assigned to receive G-CSF starting day +1 or +6 after allogeneic BMT [43]. Reducing the length of treatment by 5 days lowered G-CSF treatment costs by 26.3% and postponing treatment with G-CSF had no influence on the hematologic recovery after allogeneic BMT [43]. Similar results were obtained in 69 patients after unrelated donor BMT randomly assigned to G-CSF starting day 0, +5, or +10 resulting in equivalent rapid neutrophil engraftment [44].

A randomized, double-blind, placebo-controlled study was performed to determine the effects of G-CSF on hematopoietic recovery after allogeneic PBHCT from related donors [45]. Fifty-four patients were randomly assigned to receive daily G-CSF at 10 μg/kg or placebo starting on the day of transplantation. The median time to achieve an ANC greater than 0.5×10^9/L was 11 days (range, 9–20 days) for patients who received filgrastim compared with 15 days (range, 10–22 days) for patients who received placebo ($p = 0.0082$). The median time to achieve a platelet count exceeding 20×10^9/L was 13 days (range: 8–35 days) for patients who received G-CSF compared with 15.5 days (range: 8–42 days) for patients who received placebo ($p = 0.79$). There were no significant differences for RBC transfusion independence, in the incidence of acute GVHD, or 100-day mortality between the groups. The authors concluded that the administration of G-CSF appears to be a safe and effective supportive care measure following allogeneic peripheral blood HCT [45].

Forty-two adult recipients of allogeneic PBHCT from HLA-matched related donors were randomized to receive G-CSF 10 μg/kg/day SC from day 1 through neutrophil recovery, or no growth factor support after transplantation [46]. There was no significant difference between the two groups in the number of CD34+ cells infused (median, 4.8 vs. 4.3×10^6/kg). GVHD prophylaxis consisted of tacrolimus and steroids for nine patients and tacrolimus and mini-methotrexate for 33 patients. The group receiving G-CSF had a shorter time to neutrophil levels above 0.5×10^9/L (day 12 vs. day 15; $p = 0.002$) and to neutrophil levels over 1.0×10^9/L (day 12 vs. day 16; $p = 0.01$) [46].

After full haplotype-mismatched HCT in humans, the application of G-CSF after transplantation markedly delayed T-lymphocyte reconstitution and omitting G-CSF led to a more rapid increase of T cells and improved anti-infectious defense in this specific situation [47].

A retrospective analysis of the EBMT addressed the use of G-CSF after allogeneic HCT in 1789 patients with acute leukemia receiving BMT and 434 patients receiving PBHCT from HLA-identical siblings from 1992 to 2002 [48]. Among the BMT and PBHCT patients, 501 (28%) and 175 (40%), respectively, were treated with G-CSF during the first 14 days after transplantation. BMT and PBHCT patients treated with G-CSF had a faster engraftment of absolute neutrophils, but platelet engraftment was slower. In the BMT patients, GVHD grades II–IV was 50% in the G-CSF group versus 39% in the controls (RR, 1.33; $p = 0.007$, in the multivariate analysis). The incidence of chronic GVHD was also increased (RR, 1.29; $p = 0.03$). G-CSF was associated with an increase in TRM (RR, 1.73; $p = 0.00016$) and had no effect on relapse but reduced survival (RR, 0.59; $p < 0.0001$) and leukemia-free survival rates (LFS; RR, 0.64; $p = 0.0003$). No such effects of G-CSF were seen in patients receiving PBHC [48].

In a single center retrospective analysis the question was asked whether G-CSF might contribute to the incidence of GVHD [49]. Two hundred and sixty patients given G-CSF prophylaxis after allogeneic hematopoietic stem-cell transplantation were compared with 205 controls transplanted between 1993 and 2003. G-CSF hastened the engraftment of neutrophils, but that of platelets was delayed ($p < 0.0001$). The proportion of acute GVHD of grades II–IV was 29% in the G-CSF group and 19% in the controls ($p < 0.01$) and that of chronic GVHD was 54% and 43%, respectively ($p = 0.019$). G-CSF increased acute and chronic GVHD in patients preferentially conditioned with chemotherapy. Unexpectedly, it exacerbated acute GVHD in recipients of peripheral blood stem cells and enhanced chronic GVHD in bone marrow recipients. A multivariate analysis showed that both acute and chronic GVHD were associated with G-CSF. There was no significant difference between study groups regarding non-relapse mortality, relapse, or survival.

This question was again addressed in a more recent retrospective analysis of the EBMT studying the effects of growth factor therapy on outcome after allogeneic HCT with >9 years of follow-up [50]. Of 1887 adult patients with acute leukemia who received bone marrow from sibling donors and were treated with myeloablative conditioning, 459 (24%) were treated with growth factor. Growth factor hastened engraftment of neutrophils ($p < 0.0001$), but reduced platelet counts ($p = 0.0002$). GVHD-free survival (no acute GVHD grade II–IV or chronic GVHD) at 10 years was 12 ± 2% (±SE) in the growth factor group, as opposed to 17 ± 2% in the controls and this effect was independent of conditioning with or withour irradiation. Non-relapse mortality (NRM) was higher in the growth factor group. Both groups had similar probabilities of leukemic relapse. Leukemia-free survival (LFS) at 10 years was 35 ± 2% in those receiving growth factor prophylaxis, as opposed to 44 ± 1% in the controls. Prophylaxis with growth factor increased the risk of GVHD, did not affect relapse, increased NRM and reduced LFS >10 years after HSCT, regardless of conditioning with TBI [50].

Summary: clinical use of G-CSF after HCT

In summary, G-CSF application after allogeneic or autologous bone marrow or peripheral blood HCT significantly accelerates the time to neutrophil engraftment. Non-randomized retrospective studies suggest that growth factor therapy may negatively influence other parameters like platelet engraftment or GVHD. This benefical effect is more prominent after BMT and is preserved when the start of G-CSF application is delayed from day +1 to +5 or to +7 after HCT. The same applies to a single injection of pegfilgastrim: responses are no different whether the drug is given on day + 1 or day + 5. Whether the long-term impact of pegfilgrastim on GVHD may be different from filgrastim or lenograstim remains to be determined, similarly whether there might be a difference between unglycosylated and glycosylated variants of the drug and whether the new biosimilars may again exhibit subtle differences. All randomized trials have failed to show a clear beneficial effect on the outcome of patients after HCT.

A meta-analysis based on 34 randomized controlled trials of prophylactic G-CSF and GM-CSF after autologous and allogeneic HCT demonstrated a reduced risk of documented infections and duration of parenteral antibiotics but not in infection-related mortality [51]. The absolute decrease in the risk of documented infection was 8% and 13 patients would need to be treated with CSFs in order to prevent one infection. Subgroup analyses regarding autologous and allogeneic HCT, the use of G-CSF and GM-CSF, or PBHCT and BMT showed similar results.

In contrast to autologous HCT, the clinical situation is more complex after allogeneic HCT and the present data do not allow definite conclusions regarding specific patient situations. Despite the retrospective character of the EBMT studies mentioned earlier, its results showing a negative influence of G-CSF after allogeneic HCT remain a caveat. The potential immune modulating effects of G-CSF on mobilized stem cell grafts as well as G-CSF application to the recipient and a possible aggravation of an "engraftment syndrome" should be kept in mind when treating patients with G-CSF after allogeneic HCT. The use of G-CSF post allogeneic transplantation is associated with increased risk of GVHD and in subgroups NRM.

Granulocyte–macrophage colony-stimulating factor

Granulocyte–macrophage colony-stimulating factor (GM-CSF) can be produced by many different cell types, particularly activated T cells. In vitro, GM-CSF promotes the growth and expansion of granulocytic and monocytic, and, in combination with EPO, also multilineage colony-forming units. Multiple functions of mature neutrophils and macrophages, such as tumoricidal activity, superoxide production, antibody-dependent cell-mediated cytotoxicity, phagocytic activity, microbial killing, and secretion of other cytokines are stimulated [52,53]. Furthermore, GM-CSF, when used in vitro, induces the differentiation of malignant antigen-presenting cells with potent T-cell stimulatory capacity [54].

In humans, GM-CSF causes a dose-dependent increase mainly in blood neutrophils and eosinophils, but also macrophages and lymphocytes. There is no effect on the erythroid or megakaryocytic lineage. After application, patients may experience low-grade fever, fatigue, myalgias, and dyspnea. After higher doses, significant fluid retention, pericarditis, pleuritis, and a capillary leak syndrome may develop [55,56].

Commercially available recombinant preparations of GM-CSF (molgramostin and sargramostim) differ in their state of glycosylation. However, this difference does not appear to be clinically relevant.

While all earlier trials have focused on time to neutrophil recovery, this objective is today almost exclusively pursued by application of G-CSF. More recent trials have almost solely addressed the effects of GM-CSF in the context of immunotherapeutic approaches.

GM-CSF after autologous HCT

In a randomized, double-blind, placebo-controlled trial, 128 patients undergoing autologous BMT for lymphoid malignancies were enrolled [57]. Fifty-six patients received GM-CSF in a 2-hour IV infusion daily for 21 days, starting within 4 hours of marrow infusion, and 63 patients received placebo. The patients given GM-CSF had a recovery of the neutrophil count to 500×10^6/L 7 days earlier than the patients who received placebo (19 vs. 26 days; $p < 0.001$), had fewer infections, required 3 fewer days of antibiotic administration (24 vs. 27 days; $p = 0.009$), and required 6 fewer days of initial hospitalization (median, 27 vs. 33 days; $p = 0.01$). There was no difference in the survival rate at day +100 after HCT [57].

Another study comparing the use of G-CSF (5 μg/kg/day) with sargramostim (GM-CSF) 500 μg/day from day 0 until neutrophil recovery (ANC > 1500/μL) in patients with breast cancer or myeloma who underwent PBHCT showed faster neutrophil recovery with G-CSF in comparison to GM-CSF [58].

GM-CSF after allogeneic HCT

GM-CSF was also tested in randomized trials after allogeneic transplantation. In a randomized double-blind trial in patients undergoing HCT for leukemia, 20 received GM-CSF and 20 received placebo, for 14 days after allogeneic, matched sibling BMT [59]. The neutrophil count recovered to 0.5×10^9/L 3 days earlier in the GM-CSF group than in the placebo group (not significant). No difference in GVHD or relapse was reported.

In a prospective randomized placebo controlled trial involving 57 patients receiving T-cell-depleted marrow transplants, GM-CSF led to higher neutrophil and monocyte counts for 6 to 10 days during the time period of 2 to 3 weeks after transplantation resulting in fewer pneumonias [60].

Long delay in hematologic recovery after BMT, especially graft failure, can extend and amplify the risks of infection and hemorrhage, compromise patients' survival, and increase the duration and cost of hospitalization. GM-CSF was evaluated in 37 patients with marrow graft failure after allogeneic ($n = 15$), autologous ($n = 21$), or syngeneic ($n = 1$) bone marrow transplantation [61]. GM-CSF was administered by 2-hour infusion at doses between 60 and 1000 μg/m^2/day for 14 or 21 days. At doses of less than 500 μg/m^2, GM-CSF was well tolerated and did not exacerbate GVHD in allogeneic transplant recipients. No patient with myelogenous leukemia relapsed while receiving GM-CSF. Twenty-one patients reached an ANC equal to or above 0.5×10^9/L within 2 weeks of starting therapy while 16 did not. None of seven patients who received chemically purged autologous marrow grafts responded to GM-CSF. The survival rates of GM-CSF-treated patients were significantly better than those of a historical control group [61].

Summary: clinical use of GM-CSF after HCT

In summary, GM-CSF accelerates neutrophil engraftment after autologous and allogeneic transplantation. However, due to a lack of advantage over G-CSF, GM-CSF is not routinely used for this purpose. GM-CSF has been used effectively in bone marrow failure states. The immunostimulating effects of GM-CSF with its capacity to differentiate antigen-presenting cells are employed with or without concomitant donor lymphocyte infusions for relapse of leukemia after allogeneic transplantation and a beneficial role of the combination of alpha-interferon and GM-CSF is suggested [62]. Furthermore GM-CSF may have a place as an adjunct in post-transplant vaccination trials and in anti-infectious strategies, for example in treating patients with invasive fungal infections by augmenting the phagocytic capacities of monocytes and macrophages. However, at this point the clinical use of GM-CSF is primarily in clinical studies in the context of post-transplant immunotherapy.

Other hematopoietic growth factors and cytokines

While many growth factors and cytokines have effects on hematopoiesis and its niche, only a few have been investigated in the context of hematopoietic cell transplantation. After initial promising preclinical results, most have been withdrawn from further clinical development because of untoward effects and lack of efficacy. The results for some of these agents are summarized here.

Interleukin-3

Interleukin-3 (IL-3), also known as multi-CSF, is a multilineage hematopoietic growth factor produced by T lymphocytes and mast cells that acts on early and committed cell populations of all lineages. In vivo, IL-3 administration is often accompanied by severe side effects with fever, malaise, chills, headache, arthralgias, and urticaria [63]. Because of these side effects, a dose-escalating study using IL-3 alone had to be stopped at 2 μg/kg/day [63]. Used alone, IL-3 did not enhance neutrophil engraftment compared to the use of GM-CSF [64].

In summary, due to the side effects and only modest positive impact on hematopoiesis, IL-3 or its modifications have not been licensed for clinical use after HCT.

Stem cell factor

Stem cell factor (SCF), also known as steel factor, kit-ligand, or mast cell growth factor promotes the proliferation and differentiation of the most primitive hematopoietic progenitor cells into committed progenitor cells. Recombinant SCF (rHuSCF, ancestim) has been developed for clinical use in combination with G-CSF to optimize stem cell mobilization from the marrow into the peripheral blood for apheresis and to provide a sustained increase in the number of HSC capable of engraftment [65]. When used for hematopoietic cell mobilization, a considerable number of patients reacted with delayed-type hypersensitivity like skin rash, dyspnea, angioedema, and cardiovascular symptoms.

No trials with the use of SCF after HCT have been published. Presently, there is no proven indication for SCF after transplantation and there is no licensed product available for clinical use.

Thrombopoietin/megakaryocyte growth factor

Thrombopoietin (TPO) stimulates the growth and differentiation of megakaryocytes and proplatelets via the receptor c-mpl. It is predominantly produced by hepatocytes and serum levels are inversely correlated with platelet counts.

Two ligands for the mpl receptor with broad in vitro megakaryocytic proliferative, maturational, and differentiation capacity have been developed and tested in clinical trials. One is a modified (PEGylated) form of a recombinant truncated mpl ligand, called megakaryocyte growth and development factor (MGDF) [66]. The other is the recombinant glycosylated version of the naturally occurring thrombopoietin (TPO) molecule [67].

In a randomized trial, 47 patients with stage II, III, or IV breast cancer undergoing autologous HCT were allocated to placebo ($n = 13$) or to one of five sequential dose cohorts of PEG-rHuMGDF ($n = 34$) resulting in a median time to platelet recovery of 11 and 12 days for the placebo and combined PEG-rHuMGDF groups, respectively [68].

The role of recombinant megakaryocyte growth factors after HCT has not been thoroughly tested and remains unclear. Furthermore, due to reports on the development of neutralizing antibodies and thrombophilia in vivo, the above-mentioned recombinant products have not been licensed for clinical use.

After the experience of these first-generation thrombopoietic growth factors, second-generation thrombopoietic factors have been developed as summarized in a review by Kuter [69]. AMG 531 is a TPO-mimetic peptide linked to human IgG fragments and weekly subcutaneous applications in healthy volunteers and patients with immune thrombocytopenia resulted in elevated platelet counts without major side effects apart from mild headache at the day of injection. This agent is now licensed under the name "romiplostin" for treatment of immune thrombocytopenia or thrombocytopenia induced by chronic liver disease, as well as the orally available small molecules eltrombopag with TPO agonistic properties [70,71].

Romiplostin was successfully used for the treatment of acute GVHD-associated thrombocytopenia [72] or prolonged thrombocytopenia after HCT [73].

Interleukin-11

Interleukin-11 (IL-11) is a naturally occurring cytokine produced by fibroblasts and bone marrow stromal cells and is a growth factor with pleiotropic effects overlapping with other growth factors. In vivo, IL-11 administration stimulates megakaryopoiesis and increases peripheral platelet and neutrophil counts [74], an effect that can be enhanced by combination with IL-3. A recombinant preparation of IL-11, oprelvekin, produced in *E. coli*, is licensed for clinical use for the prevention of severe thrombocytopenia and the reduction of the need for platelet transfusions following myelosuppressive chemotherapy. Major side effects include fluid retention and edema.

A placebo-controlled randomized trial with 80 breast cancer patients tested the effects of recombinant IL-11 on platelet recovery after high-dose chemotherapy and autologous transplantation with peripheral blood hematopoietic cell support. The results did not demonstrate that rhIL-11 treatment significantly decreased platelet transfusion [75].

In a randomized double-blind pilot study, IL-11 was administered with cyclosporine/MTX prophylaxis after cyclophosphamide/TBI conditioning and allogeneic stem cell transplantation for hematologic malignancies [76]. Patients received IL-11, 50 μg/kg/day SC or placebo. Only 13 patients (10 IL-11, three placebo) were enrolled because the early stopping rule for mortality was enforced. Of 10 evaluable patients who received IL-11, four died by day 40 and one died on day 85. Deaths were attributable to transplant-related toxicity. Patients receiving IL-11 had severe fluid retention and early mortality, making it impossible to determine whether IL-11 given in this schedule can reduce the rate of GVHD. Grade II–IV acute GVHD occurred in two of eight evaluable patients on IL-11 and one of three patients on placebo. The primary adverse events of the study were severe fluid retention resistant to diuresis (average weight gain 9 +/– 4%) and multiorgan failure in five of 10 evaluable patients. The authors concluded that IL-11 as administered in this trial for GVHD prophylaxis in allogeneic transplantation cannot be recommended [76].

In view of these marginal benefits and the serious side effects of IL-11, no further trials have been reported in recent years.

Cytokines and growth factors for immunotherapy after transplantation

While many cytokines and growth factors for immunotherapy after transplantation have been studied in preclinical settings, only a few have entered the clinical stage.

Preclinical studies and in some cases early clinical studies have shown that exogenous keratinocyte growth factor (KGF), IL-7, Flt-3 ligand (Flt3L), and growth hormone (GH), IGF-1, IL-7, IL-15, and IL-12 may protect the thymus, enhance thymic cellularity, and enhance post-transplant recovery of T cells in various experimental settings. Of these, only KGF has been approved by the US FDA for the prophylaxis of mucositis in recipients of high-dose chemotherapy (including HCT).

GM-CSF for immunotherapy after transplantation

A variety of early clinical trials in patients with various hematologic malignancies and solid tumors has investigated the post-transplant application of GM-CSF, frequently in combination with IL-2 as well as monoclonal antibodies directed against cancer cells. All studies demonstrated feasibility with acceptable toxicity, enhanced in vitro immune responses, for example in cytotoxicity assays, but failed to demonstrate a clinical benefit.

Interleukin-2

Interleukin-2 (IL-2) is produced by activated T lymphocytes and is an important regulator of the immune system acting on T-, B-, and NK cells. IL-2 knockout mice develop T cells normally, but they suffer from generalized fatal immunoproliferative disorders and loss of self-tolerance.

Recombinant IL-2, aldesleukin, is licensed for the treatment of metastatic renal cell carcinoma. Several phase II trials that used IL-2 after autologous HCT for patients with lymphoma or AML as an immunomodulator to reduce relapse rates demonstrated feasibility; however, without large randomized trials the role of IL-2 in the context of autologous HCT remains unclear.

In a pilot trial the effects of low-dose IL-2 treatment in 12 patients with metastatic cancer and 9 patients with chronic myeloid leukemia after allogeneic HCT was examined [77]. Overall, IL-2 treatment resulted in a 1.9-median-fold increase in the frequency of $CD4^+CD25^+$ cells in peripheral blood as well as a 9.7-median-fold increase in FOXP3 expression in $CD3^+$ T cells [77]. Successful treatment with IL-2 0.5 mIU/m^2/day continuous IV of a patient with progressive multifocal leukencephalopathy developing after allogeneic HCT was reported [78], highlighting the role of IL-2 as a potent immunomodulator after allogeneic HCT. As discussed earlier, the stimulation of APC by G-CSF and expansion of T effector cells by IL-2 is being investigated in several early clinical trials. IL-2 is also used to enhance engraftment and expansion of adoptively transferred T and NK cells [79].

IL-2 was combined with donor lymphocyte infusion (DLI) after chemotherapy in patients with relapsing leukemia after allogeneic HCT [80]. Seventeen patients received DLI (1×10^8 CD3/kg for patients with related donors, and 0.1×10^8 CD3/kg for those with unrelated donors) and an escalating dose of induction IL-2 [1.0, 2.0, or 3.0×10^6 IU/m^2/day representing levels I ($n = 7$), Ia ($n = 9$), and II ($n = 1$)] for 5 days followed by maintenance (1.0×10^6 IU/m^2/day) for 10 days as a continuous intravenous infusion. Unacceptable IL-2-related toxicities developed in one patient at level I, two at level Ia, and one at level II. Grades III–IV acute graft-versus-host disease (aGVHD) developed in five patients, and extensive chronic GVHD (cGVHD) developed in eight. Eight patients had a complete remission after chemotherapy prior to DLI, and two additional patients had a complete remission after DLI plus IL-2 therapy. The authors concluded, that the maximal tolerated induction dose of IL-2 combined with DLI appears to be 1.0×10^6IU/m^2/day, and IL-2 administration after DLI may increase the incidence of cGVHD [80].

Another strategy for administration of IL-2 at low doses is the attempt to restore the balance of the immune system by expanding regulatory T cells [81]. In an observational cohort study, patients with cGVHD that was refractory to glucocorticoid therapy received daily low-dose subcutaneous IL-2 (0.3×10^6, 1×10^6, or 3×10^6IU per square meter of body-surface area) for 8 weeks. After a 4-week hiatus, patients with a response could receive IL-2 for an extended period. A total of 29 patients were enrolled. None had progression of chronic GVHD or relapse of a hematologic cancer. The maximum tolerated dose of IL-2 was 1×10^6IU per square meter. The highest dose level induced unacceptable constitutional symptoms. Of the 23 patients who could be evaluated for response, 12 had major responses involving multiple sites. The numbers of CD4+ Treg cells were preferentially increased in all patients, with a peak median value, at 4 weeks, that was more than eight times the baseline value ($p < 0.001$), without affecting $CD4^+$ conventional T (Tcon) cells. The Treg : Tcon ratio increased to a median of more than five times the baseline value ($p < 0.001$). The Treg cell count and Treg : Tcon ratio remained elevated at 8 weeks ($p < 0.001$ for both comparisons with baseline values), then declined when the patients were not receiving IL-2. The increased numbers of Treg cells expressed the transcription factor forkhead box P3 (FOXP3) and could inhibit autologous Tcon cells. Immunologic and clinical responses were sustained in patients who received IL-2 for an extended period, permitting the glucocorticoid dose to be tapered by a mean of 60% (range, 25 to 100). The authors concluded, that daily low-dose IL-2 was associated with preferential, sustained Treg cell expansion in vivo and amelioration of the manifestations of chronic GVHD in a substantial proportion of patients [81].

Keratinocyte growth factor

Keratinocyte growth factor (KGF), also called fibroblast growth factor 7 (FGF-7), is a mediator of epithelial cell proliferation and a growth factor for hepatocytes and pneumocytes. KGF is naturally produced in mesenchymal cells and acts on a wide variety of epithelial cells. KGF has been shown to be protective in radiation- or chemotherapy-induced organ damage. In murine models of allogeneic transplantation it protected the gut from lethal GVHD [82]. Furthermore, pharmacologic doses of KGF allow regeneration of GVHD-induced thymic damage and therefore KGF appears to exert a potent effect on thymic epithelial cell function, which in turn allows for normal T lymphopoiesis to occur during acute GVHD [83].

Palifermin, the N-truncated form of recombinant human keratinocyte growth factor-1, is available for the prevention of mucosal damage after intensive chemo- or radiation therapy [84]. Several studies have shown the beneficial effects on oral and intestinal mucositis [85].

An interesting case report also suggests a therapeutic benefit in the treatment of post-transplant cystitis [86].

KGF in autologous HCT

In a case series of patients treated prophylactically with KGF during high-dose chemotherapy and autologous HCT, reduction of severe oral mucositis and related symptoms but not infections, dietary intake, time to engraftment, or cumulative dose and duration of narcotic administration compared to patients without KGF treatment, was observed [87].

KGF proved to significantly reduce duration and severity of oral mucositis after high-dose TBI-containing therapy in randomized trials [88,89]. In one trial KGF 60 μg/kg/day was given for 3 days prior to TBI and at days 0, 1, and 2 after transplantation and the incidence of oral mucositis of World Health Organization (WHO) grade 3 or 4 was 63% in the KGF group and 98% in the placebo group ($p < 0.001$) The median duration of oral mucositis of WHO grade 3 or 4 was 3 days (range, 0 to 22) in the KGF group and 9 days (range, 0 to 27) in the placebo group ($p < 0.001$) and patients reported less soreness and use of opioid analgesics in the KGF group [89]. Side effects were skin rash, pruritus, erythema, and taste alteration with mild to moderate severity, and were transient.

In all clinical studies in autologous HCT a beneficial effect on mucositis has been observed. However, no survival benefit was seen in any of these studies [90–92].

KGF in allogeneic HCT

KGF was tested in a randomized, double-blind, placebo-controlled, dose-escalation study regarding safety, engraftment, and influence on GVHD ($n = 69$ patients) as compared to placebo ($n = 31$) in patients conditioned with Cy/TBI or Bu/Cy and given methotrexate along with a calcineurin inhibitor (cyclosporine, tacrolimus) for GVHD prophylaxis. All patients received three doses before conditioning and either three (cohort 1), six (cohort 2), or nine (cohort 3) doses after HCT. Palifermin doses were 40 μg/kg/day (cohort 1 only) or 60 μg/kg/day (all cohorts). Six patients (two on placebo, four on palifermin) experienced a total of 11 dose-limiting toxicities (most often skin, respiratory, or oral mucositis). The most common adverse events included edema, infection, skin pain, or rash. Palifermin was associated with reduced incidence and severity of mucositis in patients conditioned with Cy/TBI but not Bu/Cy. KGF was regarded as safe in allogeneic HCT but had no significant effect on engraftment, acute GVHD, or survival in this trial [93]. With longer follow-up there were no additional differences between the palifermin-treated and placebo cohorts with respect to CMV or invasive fungal infections, chronic GVHD, or long-term survival between cohorts [94].

The question of immune reconstitution after allogeneic HCT was addressed by a follow-up analysis [95]. It was investigated whether palifermin-treated patients ($n = 69$) had improved absolute lymphocyte counts (ALCs) at days 30, 60, and 100 after transplant compared to placebo-treated patients ($n = 31$). No statistically significant difference in ALC was noted at these time points. Additionally, there was no difference in ALC between patients who received low- (240 μg/kg) versus high- (720 μg/kg) dose palifermin. Patients with a day 30 ALC of $>600 \times 10^6$/L had a trend towards improved progression-free survival (49% vs. 29%; $p = 0.07$), lower transplant-related mortality (18% vs. 35%; $p = 0.1$), and grade II–IV aGVHD (31% vs. 47%; $p = 0.14$), but this was not influenced by palifermin therapy. In contrast to animal studies, peri-transplant palifermin did not accelerate early lymphocyte recovery following myeloablation and a T-replete allogeneic graft.

In a multicenter study, 30 patients undergoing matched related or unrelated allogeneic HCT for leukemia were treated with palifermin, and retrospectively compared to a matched control group [96]. Palifermin recipients transplanted with an unrelated donor showed a significant reduction of severity, incidence, and duration of oral mucositis WHO grades 2–4. In addition, in the palifermin group the use of opioid analgesics and the duration of total parenteral nutrition decreased, whether stem cells were used from matched related or unrelated donors. No beneficial influence of palifermin on the incidence and severity of aGVHD was apparent. The incidence and duration of febrile neutropenia, documented infections, hematopoietic recovery, or overall survival (OS) remained unchanged. The most common adverse effects included rash or erythema, generally mild and transient in appearance. In a multicenter, non-randomized, matched-control study no difference for early OS, incidence and severity of acute and chronic GVHD was observed in 36 patients with hematologic diseases treated with allogeneic HCT and palifermin [97].

The benefits of palifermin appear primarily to be limited to ameliorating mucotoxicity when given to allogeneic HCT recipients with no additional benefits on morbidity or survival.

Conclusion

In several situations hematopoietic growth factors have a defined role after HCT. In particular, randomized trials documented faster erythroid engraftment with EPO after allogeneic BMT, and G-CSF resulted in accelerated neutrophil engraftment after allogeneic and autologous marrow as well as peripheral blood hematopoietic cell transplantation. Regarding other endpoints the results are equivocal. The value of these growth factors given after HCT has to be seen in the light of pros and cons of the individual patient and specific transplant situation. Faster engraftment is only one aspect and other factors, such as days in hospital or in isolation, transfusion requirements, possible cytokine-induced engraftment syndromes, or influence on the immune system, especially increased rates of GvHD after allogeneic HCT, as well as costs have to be taken into consideration. Studies using other cytokines are continuing. The benefits of all agents appear to be in the area of supportive care, while survival benefits have yet to be demonstrated.

CHAPTER 44

Hematopoietic Cell Transplantation from Human Leukocyte Antigen Partially Matched Related Donors

Claudio Anasetti[1], **Franco Aversa**[2] **and Andrea Velardi**[3]

Introduction

Hematopoietic cell transplantation (HCT) from human leukocyte antigen (HLA)-matched siblings has become the treatment of choice for many hematologic diseases, but fewer than 40% of patients have an HLA-matched sibling [1]. Registries of HLA-typed volunteers have been established worldwide to provide HLA-matched unrelated donors for HCT (see Chapter 45). The chance of finding an unrelated donor matched for HLA-A, -B, -C, and -DR depends on the HLA diversity of the population and varies with race, ranging from 65% in Caucasians to less than 20% for US ethnic minorities [2,3]. Umbilical cord blood offers the advantages of easy procurement, no risk to the donors, low risk of transmissible infections, and immediate availability of the cryopreserved graft (see Chapter 39). However, engraftment is a major concern when the harvested cord blood contains a low number of mononuclear cells. Older patient age and HLA disparity are poor risk factors for engraftment and survival after transplantation of unrelated cord blood hematopoietic cells [4,5].

An alternative source of hematopoietic cells is from relatives who are partially matched for HLA antigens. Almost all patients have at least one HLA partially matched family member, parent, sibling, or child, who is immediately available as donor. Transplants of T-replete marrow or growth factor-mobilized peripheral blood progenitor cells (PBPCs) from relatives mismatched for a single HLA-A, -B, or -DR antigen have met with acceptable success rates using standard protocols commonly employed for transplants from HLA-identical siblings [6,7]. Conversely, transplants of T-replete marrow from donors mismatched for two or three HLA-A, -B, and -DR antigens have resulted in an extremely high incidence of severe acute graft-versus-host disease (GVHD) when patients receive postgrafting immunosuppression with methotrexate alone or in combination with calcineurin inhibitors [6,8]. A variety of approaches for ex vivo or in vivo T cell depletion has decreased the incidence of acute and chronic GVHD and has permitted long-term survival after HCT from highly mismatched relatives [9–12].

In this chapter, we first present principles for the selection of related donors with the least degree of HLA disparity, and later present more recent developments in the field of GVHD prevention after transplants from incompatible relatives.

Donor selection

Function and polymorphism of HLA

The HLA system (described in detail in Chapter 10) includes at least 12 genetic sites, named HLA loci, located on the short arm of human chromosome 6. Each HLA locus is highly polymorphic because it is occupied by multiple alternative forms of an HLA gene, designated HLA alleles, any of which may be carried by a given individual. HLA alleles encode class I HLA-A, -B, and -C antigens, and class II HLA-DR, -DQ, and -DP antigens. Each of these genes regulates transplantation responses [6,13–16]. Class I HLA antigens are expressed on the surface of all nucleated cells in the body, while class II HLA antigens are expressed on the surface of antigen-presenting cells (APCs) such as dendritic cells, monocytes, B cells, and activated T cells. It is the function of HLA molecules to bind antigenic peptides and activate the immune response in a specific manner. In order to accommodate the need for the binding of ever-changing environmental and microbial antigens, HLA molecules have evolved through gene duplication, gene conversion, recombination, and point mutation to acquire an enormous degree of polymorphism, most evident across different ethnic groups.

Class I HLA molecules present antigenic peptides and activate cytotoxic CD8 T cells, while class II HLA molecules present antigenic peptides and activate helper CD4 T cells. Both classes of HLA molecule lead to T-cell activation through the binding of specific T-cell antigen receptors. In the case of HLA-incompatible HCT, donor and recipient differ not only for one or more types of HLA molecule, but also for the thousands of antigenic peptides that each mismatched HLA molecule can bind and present to foreign T cells [17]. By this process, HCT leads to the activation of an enormous number of donor T cells that mount a response against the host and vice versa. The strength of the immune response depends on the degree of HLA mismatch. T-cell recognition of antigenic peptides presented by mismatched HLA molecules can result both in GVHD and graft rejection. Low levels of T-cell recognition define "permissible" mismatches, and these have been associated with improved transplantation outcomes when compared to "non-permissible" mismatches [15,18,19].

HLA class I molecules also bind specific receptors on natural killer (NK) cells. Recent developments on the role of NK cells in transplantation are presented later in this chapter, in the section on T-depleted grafts, where the effects of NK cell function have become apparent. HLA class I and II molecules also function as antigens by eliciting antibody responses by B cells. It is thought that

anti-HLA antibodies can mediate a hyperacute rejection of allogeneic HCTs [20].

HLA haplotypes and segregation in families

The HLA antigens inherited together from one chromosome of each parent are referred to as an HLA haplotype (Figure 44.1). When a family study is performed in search of an HLA-identical sibling donor, parents should also be typed for HLA-A, -B, and -DR, and each of the four parental HLA haplotypes identified. Parental haplotypes can segregate among the offspring in four different combinations, and the chance that any one sibling is HLA identical with another is 25%. If an HLA-identical sibling is not found, it is possible to find family members who are partially matched for HLA, even though they have not inherited the same two haplotypes, because certain HLA antigens and haplotypes are frequent. The parental haplotypes should be reviewed for homozygosity or sharing of antigens. The parents, siblings and children, and other relatives who share a haplotype with the patient may have a second haplotype that is partially matched with the patient.

Figure 44.1(a) illustrates a family in which the parents have matching haplotypes, "b" and "c." The patient (sib 1, "a/c") has a unique HLA type, and none of the siblings is HLA identical with the patient. However, the patient and the father ("a/b") share the paternal "a" haplotype and are matched for the HLA-A, -B, and -DR antigens of their unshared haplotypes ("b" and "c"). Figure 44.1(b) illustrates a family in which the mother ("c/d") is HLA homozygous. The patient (sib 1, "a/c") and sib 2 ("a/d") share the paternal "a" haplotype and each has inherited one of the two maternal haplotypes ("c" and "d"). Because of the serendipitous similarity of the maternal "c" and "d" haplotypes, sib 1 and sib 2 are HLA matched.

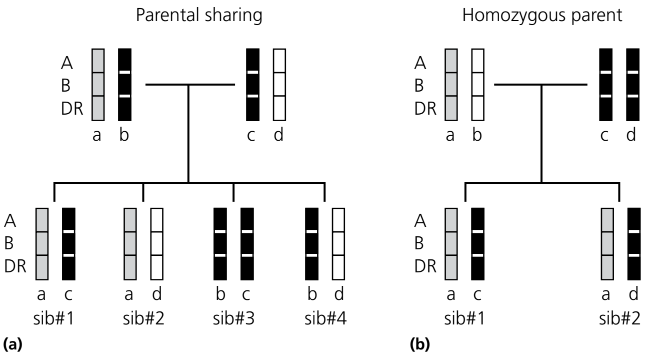

Figure 44.1 Segregation of human leukocyte antigen (HLA) haplotypes and partial sharing of HLA antigens within a family. (a) The two parental haplotypes "b" and "c" are identical, so that sibling 1 (haplotypes "a" and "c") is compatible with one of these parents (haplotypes "a" and "b"). (b) One parent is HLA homozygous (haplotype "c" and "d" being identical), so that sibling 1 (haplotypes "a" and "c") and sibling 2 (haplotypes "a" and "d") are compatible.

In haploidentical sibling HCT, the mismatched haplotype can originate from either of the parents. In Figure 45.1(a), the patient (sib 1, "a/c") is mismatched with sib 2 ("a/d") for non-inherited paternal antigens (NIPA) on haplotypes "c" versus "d," while another patient ("a/d" that is not shown) is mismatched with sib 4 ("b/d") for non-inherited maternal antigens (NIMA) on haplotype "a" versus "b." Donor exposure to non-inherited maternal HLA antigens benefits patients undergoing bone marrow transplantation. In one study, sibling transplantations mismatched for NIMA had similar rates of graft failure but lower rates of acute GVHD ($p < 0.02$) than those mismatched for NIPA [21]. Mother-to-child transplantations were associated with improved outcomes than father-to-child transplantations in some but not all studies [21–23].

Donor and recipient matching

Potential donors are those relatives who share by inheritance one HLA haplotype with the patient and are variably mismatched for 0, 1, 2, or 3 HLA-A, -B, and -DR loci of the unshared haplotype. A more precise classification of matching, useful in predicting the risk of rejection and GVHD after HLA-incompatible T-replete transplants, takes into consideration the vector of incompatibility in situations where donor or recipients are homozygous at one of the mismatched loci (Table 44.1) [8]. If recipient and donor are overall incompatible for one HLA locus but the recipient is homozygous at the mismatched locus, the mismatch does not contribute a risk for GVHD [8,24]. Because HLA-homozygous recipients are matched with their donors in the direction of GVHD, transplants incompatible for one HLA locus in homozygous recipients are associated with lower incidence of acute GVHD than in heterozygous recipients (Figure 44.2) [8]. The incidence of acute GVHD for homozygous recipients of one-locus-incompatible transplants is similar to that seen in HLA-matched transplants. Conversely, if recipient and donor are overall incompatible for one HLA locus but the donor is homozygous at the mismatched locus, the mismatch does not contribute a risk for graft rejection [20,25].

DNA sequencing can distinguish thousands of distinct HLA alleles, each designated from a letter that represent the locus followed by an asterisk and a unique number with two doublets separated by colons (i.e., HLA-A*02:01). Many alleles are expressed with a unique

Table 44.1 Mismatching according to vector of genetic disparity for human leukocyte antigen (HLA)-A, -B, and -DR

Example	Haplotype	Recipient	Donor*	Vector†		
				Overall	Rejection	Graft-versus-host disease
Heterozygous recipient and donor	Mismatched	**A2**, **B44**, **DR7**	**A3**, **B7**, **DR2**	3	3	3
	Shared*	A1, B8, DR3	A1, B8, DR3

Incompatible antigens are represented in bold.
*Recipient and donor are related and share HLA haplotype.
†Number of mismatches at HLA-A, B or DR loci.

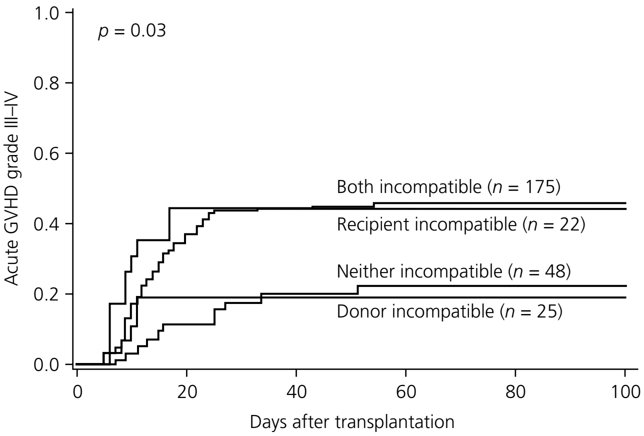

Figure 44.2 Effect of the vector of human leukocyte antigen (HLA) mismatch on acute graft-versus-host disease (GVHD). Probability of grade III–IV acute GVHD in patients who received a marrow transplant from a haploidentical relative. Transplants incompatible for one HLA-A, -B or -D/DRB1 locus are classified as "donor incompatible" in the case of homozygous recipients where mismatch is only in the direction of graft-versus-host, as "recipient incompatible" in the case of homozygous donors where mismatch is only in the direction of host-versus-graft, and as "both incompatible" in the case where donor and recipient are both heterozygous. Transplants from a haploidentical relative whose unshared haplotype is matched to that of the patient are classified as "neither incompatible."

amino acid sequence (i.e., HLA-A*02:01 vs. A*02:02) (see http://www.ebi.ac.uk/ipd/imgt/hla for the updated list of alleles; accessed February 3, 2015) [26]. Some HLA alleles have synonymous substitutions that result in expression of the same amino acid sequence and are indicated by a third doublet (i.e., HLA-A*02:03:01 vs. A*02:03:03) and therefore are matched for the purpose of donor selection. Some other unique HLA-A*02 alleles are not expressed as proteins (e.g., A*02:53N), they are instead defined as "null" and are immunologically silent. Once a null allele is identified, it should be ignored for donor selection. Distinction between alleles with highly similar sequence is important because those disparities are functionally relevant: for example, seven of the B*27 alleles can be distinguished by specific cytotoxic T-cell clones [27].

The relevance of HLA incompatibility between donor and recipient has been analyzed in patients with hematologic disorders who received HCTs of T-replete marrow grafts and an identical regimen of postgrafting immune suppression. The patient and related donor shared one HLA haplotype, hence haploidentical, but differed to a variable degree for the HLA-A, -B, and -DR antigens of the unshared haplotype. The results of these transplants have shown the effect of HLA incompatibility on GVHD, graft failure and survival, formally demonstrating that HLA antigens constitute the major histocompatibility complex (MHC) in humans. The clinical importance of subtle HLA-A, -B, -C, and -DRB1 allelic differences was demonstrated in studies of unrelated donor HCT where such mismatching (i.e., HLA-B*27:02 vs. B*27:03) was associated with increased GVHD and worse survival [14,28,29]. Increasing evidence has related DPB1 mismatching with graft failure, acute GVHD, protection from leukemia relapse, and overall mortality [15,30–34]. The relevance of donor disparity for DQB1 to GVHD has been confirmed, but its relevance to the post-transplant survival of patients with malignancy remains disputed [16,34,35].

Donor-specific antibodies

Patients may be alloimmunized by pregnancy or blood transfusions, and sensitization to donor alloantigens increases the risk of graft failure [20,36–38]. Donor-specific antibodies denote that the recipient has been sensitized to HLA antigens of the donor, and is indicated before the selection of an HLA-mismatched donor for HCT. Standard assays for crossmatching the patient's serum with donor lymphocytes include complement-dependent microcytotoxicity and multicolor flow microfluorimetry [39,40]. If complete patient and donor HLA genotyping is available, HLA-specific antibodies can be detected by enzyme-linked immunosorbent assay, flow cytometry or Luminex technologies that are more sensitive and have replaced the more cumbersome direct crossmatch [41–43]. Prior patient immunization to donor HLA antigens has a profound effect on engraftment. In a study of marrow transplants from HLA-incompatible relatives, graft failure occurred in 13 of 21 (62%) patients with a positive pre-transplant crossmatch of patient serum reactive against donor T or B lymphocytes, compared with 31 of 501 (7%) patients with a negative crossmatch ($p = 7.8$, E-10) [20,44]. Alloimmunized patients who tested positive for anti-HLA antibodies by screening against a random cell panel but were negative for donor-specific antibodies were not at increased risk of graft failure [40]. Ottinger et al. [36] also found that donor-specific antibodies predict graft failure and poor survival after peripheral blood HCT from an HLA-mismatched donor. In unrelated donor transplantation, flow cytometry and Luminex technology can detect patient antibodies specific against the donor mismatched HLA alleles and predict for graft failure [37,38]. In the presence of donor-specific antibodies, graft failure is likely the result of alloimmune rejection mediated both by sensitized radioresistant host T cells and by antibody-dependent cell-mediated killing. Removal of antidonor antibody through a plasma exchange followed by cyclophosphamide (CY) (120 mg/kg) and total body irradiation (TBI) (1200–1575 cGy), the addition of total lymphoid irradiation (600 cGy) or antithymocyte globulin (ATG) (60 mg/kg) to the standard regimen of CY and TBI has not resulted in consistent marrow engraftment [20,44]. Other more promising approaches tested include the administration of platelet transfusions, intravenous immunoglobulin, and post-transplant cyclophosphamide followed by tacrolimus and mycophenolate mofetil, but their efficacy remains to be validated [45,46]. If a patient has antibodies against an HLA-incompatible family donor, there is no consistently effective measure to offset the risk of graft rejection, and the best option for engraftment is to identify an HLA-matched unrelated donor, or a related or unrelated donor that is mismatched for an HLA antigen against which the patient is not sensitized.

Probability of identifying an HLA partially compatible family donor

One report from Germany found that the probability of identifying an HLA-matched sibling was 40.7%, a matched relative 4.0%, a one HLA-A, -B, or -DR locus-mismatched sibling 3.1%, and a one-locus mismatched relative 10.4% [1]. The best chance of finding a closely matched donor for patients without an HLA-matched or a one-locus-mismatched sibling is an unrelated donor search, because this is currently successful in up to 65% of cases [2,3]. If the initial search identifies one or more HLA-A, -B, and -DR matched unrelated donors, there is no obvious justification to undertake an extended family search beyond siblings, because not only would the probability of finding a suitable donor be lower, but also the donor typing effort and the cost of finding donors would be greater [1]. Computer programs and registry search algorithms have been developed that calculate the probability of finding a suitable related or unrelated donor based on patient typing [1,2,47,48], and the results of such programs can be utilized to define the best search strategy for an individual patient. Candidates for allogeneic HCT with no suitably matched donor and a short life expectancy might be better served by immediate transplantation from a relative mismatched for one entire HLA haplotype, or by a partially matched unrelated umbilical cord blood transplant, than by a lengthy search for a completely matched donor.

Transplantation of T-replete marrow grafts

GVHD prophylaxis with methotrexate, calcineurin inhibitors, or both

After HCT from partially matched relatives, the incidence and severity of acute GVHD correlates with the degree of HLA incompatibility for HLA-A, -B, and -DR. When patients received methotrexate (MTX) as single agent for GVHD prophylaxis, the incidence of grades II–IV GVHD was 34% for recipients of HLA-identical sibling marrow and increased progressively up to 84% for recipients of HLA-A, -B, and -DR locus-incompatible marrow [6]. Acute GVHD occurs early after HLA-incompatible transplants. The median onset of acute GVHD was 14 days after HLA-incompatible transplants, compared with 22 days after HLA-identical sibling transplants [6]. The use of cyclosporine (CSP) alone as GVHD prophylaxis after HLA-incompatible transplants was associated with a hyperacute syndrome characterized by fever 7–10 days after transplantation, fluid retention, low central venous pressure, low serum albumin, pulmonary edema, and renal failure (see Chapter 83). If other immunosuppressive agents could not reverse the syndrome, patients died from respiratory failure and other complications [49]. When it became apparent that the combination of CSP and MTX was superior to either agent alone in HLA sibling transplants, the same regimen was adopted for HLA partially matched transplants. The risk of severe acute GVHD of grade III–IV was significantly less and the time of onset was delayed by the use of CSP and MTX [relative risk (RR) 0.35; $p < 0.0001$]. The incidence of severe grade III–IV acute GVHD was decreased from 53% to 28% in one-locus-incompatible recipients and from 63% to 47% in two-locus-incompatible recipients. In a multivariate analysis of 474 patients who received CSP and MTX or MTX alone and achieved sustained engraftment, HLA incompatibility remained a significant risk factor for acute GVHD (RR 1.95 per HLA locus; $p < 0.0001$) [8,44]. Substituting CSP with tacrolimus was not adequate to prevent GVHD after transplantation from HLA-DR-incompatible relatives [50]. Post-transplant immunosuppression with CSP and MTX compared with MTX alone has not resulted in improved outcome after transplants incompatible at two or three HLA loci [8]. Therefore, despite post-transplant immunosuppression with CSP and MTX, HLA incompatibility has remained an important risk factor for GVHD (Figure 44.3) [8].

Marrow transplants from HLA partially matched family members have been associated with a higher probability for developing clinical extensive chronic GVHD (49% vs. 33%) and an earlier median day of onset (159 vs. 201 days) compared with transplants from HLA-identical siblings [51]. Consistent results have been found by the CIBMTR [52]. The duration of immunosuppressive treatment for chronic GVHD is prolonged after HLA disparate-donor transplants, with a hazard ratio of 0.8 (95% CI 0.7–0.9) per mismatched HLA locus ($p = 0.007$) [53].

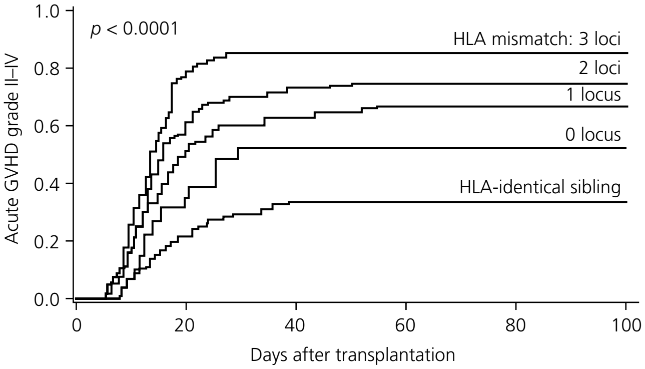

Figure 44.3 Effect of donor and recipient human leukocyte antigen (HLA) mismatch on acute graft-versus-host disease (GVHD). Probability of grade II–IV acute GVHD according to the degree of matching for HLA-A, -B, and -D/DRB1 in patients transplanted from a haploidentical relative or an HLA genotype-identical sibling. Patients received unmodified marrow and methotrexate plus cyclosporine for GVHD prophylaxis.

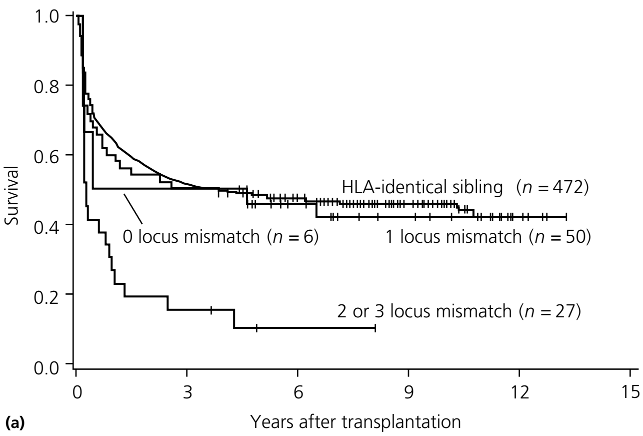
Survival in patients receiving post-transplant immunosuppression with MTX alone was similar after transplantation from an HLA-identical sibling or a one-HLA antigen-incompatible family donor. However, survival was lower in patients transplanted from a family donor incompatible for two or three HLA loci [6]. Subsequent studies of patients whose post-transplant immunosuppression consisted of CSP and MTX also showed that the degree of overall HLA incompatibility was inversely correlated with the probability of survival (Figure 44.4). Survival was predicted more precisely by matching classified according to the degree of overall incompatibility than to the incompatibility for each vector alone, because the degree of overall incompatibility best reflects the risks of both graft rejection and GVHD. In a multivariate proportional hazard regression analysis, the factors associated with lower survival were leukemia in marrow relapse at the time of transplant, and the degree of overall HLA incompatibility between donor and recipient. Post-transplant immunosuppression with CSP and MTX compared with MTX alone did not have a beneficial effect on survival.

Pre-transplantation alemtuzumab

Humanized anti-CD52 antibody alemtuzumab (100 mg over 5 days) was added to fludarabine (120 mg/m^2 over 4 days) and CY (2000 mg/m^2 over 4 days) to develop an immune-suppressive regimen that does not produce myeloablation. With T-replete PBPC transplantation from HLA partially matched related donors, primary engraftment was achieved in 46 of 49 (94%) patients, and secondary graft failure occurred in four (8%) patients, so overall sustained engraftment was 86% [54]. The incidence of acute GVHD of grades II–IV was 16%, suggesting that a large fraction of donor T cells infused in the graft were depleted by alemtuzumab in vivo [54]. The benefits of a reduced-intensity conditioning regimen were the relatively low (31%) non-relapse mortality and low (16%) incidence of grades II–IV acute GVHD.

Pre-transplantation polyclonal anti-T-cell therapy, PBPC, and post-transplantation mycophenolate mofetil

Huang and other investigators from Peking University (Beijing, China) utilized rabbit ATG (Thymoglobulin) 10 mg/kg over 4 days, or porcine ATG 80 mg/kg over 4 days before the transplant of T-replete marrow cells plus PBPCs from HLA partially matched



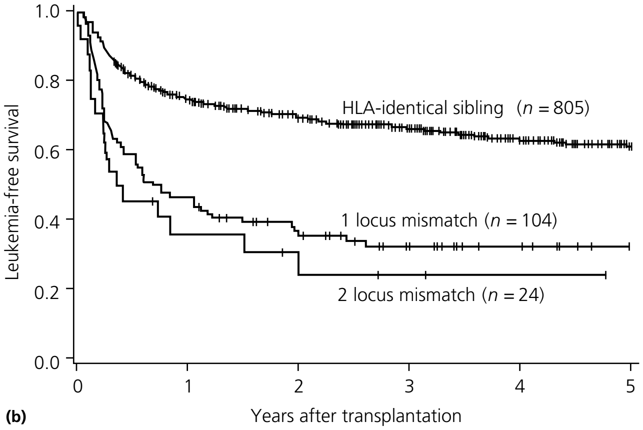


Figure 44.4 Effect of donor and recipient human leukocyte antigen (HLA) mismatch on survival after hematopoietic cell transplantation. Probability of survival in patients with chronic myeloid leukemia in chronic phase, acute myeloid leukemia in first remission or acute lymphoblastic leukemia in first or second remission, according to the degree of donor and recipient HLA incompatibility. (a) Results from a single-center study. Source: Anasetti et al. 1990 [8]. Reproduced with permission of Elsevier. (b) Results from a study of the International Bone Marrow Transplant Registry. Source: Szydlo et al. 1997 [52].

related donors, and post-transplant immune suppression with MTX/CSP plus mycophenolate mofetil [55]. All 171 patients achieved full donor chimerism and hematopoietic reconstitution. Acute GVHD grade II–IV and III–IV was observed in 55% and 23% of patients, respectively, with no suggestion for an association between degree of HLA disparity and risk of acute GVHD. Intriguing results were reported by Lu and collaborators using ATG treatment before T-cell-replete marrow or PBPC transplantation from HLA partially matched relatives. The 2-year incidence of chronic GVHD was 55% (95% CI 46–64%) after mismatched HCT with ATG compared with 56% (95% CI 47–64%) after HLA-identical sibling HCT with no ATG (p = 0.9) [56]. A separate report from the same institution compared the outcome of HLA partially matched transplants in patients pretreated with Thymoglobulin with the outcome of HLA-matched sibling transplants, without Thymoglobulin. All patients received the same postgrafting immune suppression with MTX/CSP plus mycophenolate mofetil. The cumulative incidences of acute GVHD grade II–IV were 32% (95% CI 25–39%) versus 40% (95% CI 32–48%) in the matched and mismatched cohorts, respectively (p = 0.13). The risk of acute GVHD grade II–IV was significantly higher, and GVHD had a more rapid onset after HLA-mismatched transplants. Clinical manifestation of grade III–IV GVHD after mismatched transplants included severe (44%) and bloody diarrhea (23%), hepatic dysfunction (41%), skin rash (31%), and non-cardiac edema (18%) [56]. While the relative contribution of pre-transplant ATG and post-transplant mycophenolate mofetil to GVHD prevention cannot be discerned from these studies, the data indicate that the administration of ATG just before HCT can deplete T cells in vivo and diminish the risk of GVHD.

The outcomes of HLA-mismatched related HCT (n = 135) for leukemia were compared with those of HLA-identical sibling HCT (n = 158) performed during the same time period in Beijing, China by Lu et al. [56]. The donor was mismatched for one (n = 21), two (n = 62), or three (n = 52) HLA-A, -B or -DR loci. All patients received conditioning with BU/CY. In addition, ATG was administered before mismatched HCT only. Unmanipulated marrow and/or PBPCs were used for transplantation. All patients received postgrafting immune suppression with MTX/CSP plus mycophenolate mofetil. All patients achieved full engraftment. The cumulative incidences of grade II–IV acute GVHD in the matched and mismatched cohorts were 32% versus 40%, respectively (multivariate p = 0.02), while chronic GVHD did not differ between the cohorts (p = 0.97) (Figure 44.5). Two-year incidences of treatment-related mortality and relapse for matched versus mismatched were 14% (95% CI 9–20%) versus 22% (95% CI 15–29%) (p = 0.10), and 13% (range 8–19%) versus 18% (range 10–27%) (p = 0.40), respectively. Two-year adjusted overall survival and leukemia-free survival were 72% (95% CI 64–79%) versus 71% (95% CI 62–77%) (p = 0.72), and 71% (95% CI 63–78%) versus 64% (95% CI 54–73%) (p = 0.27), respectively (Figure 44.5). Multivariate analyses showed that advanced disease stage and a diagnosis of acute leukemia had an increased risk of relapse, treatment failure, and overall mortality, whereas donor HLA mismatch did not affect these outcomes.

A long-term follow-up of HLA-mismatched related HCT using the Beijing regimen extended the favorable initial findings of Huang and Lu on more than 700 patients [11]. In addition, HLA-mismatched related HCT proved superior to chemotherapy alone as post-remission treatment for patients with acute myeloid leukemia in first complete remission [57]. Results from two additional trials from Lee et al. in Korea, and Di Bartolomeo et al. from Italy largely reproduced the data from Huang and Lu [58,59]. Whereas the effectiveness of the Beijing regimen was verified by these two external trials, it remains unclear whether each of its components is key to success. A large controlled trial by Finke et al. demonstrated that administration of polyclonal T-cell specific antibodies before HCT from HLA-matched unrelated donors is effective in preventing acute and chronic GVHD [60,61]. Antibody preparations vary in potency and safety, but all data from randomized trials taken together indicate that ATG preparations are biologically active in the prevention of GVHD [62]. Therefore, ATG is very likely contributing to the prevention of GVHD after HLA-mismatched HCT.

G-CSF mobilized blood stem cells are rich in both hematopoietic progenitors and T cells and are more consistent in achieving engraftment compared to bone marrow in unrelated donor transplantation [63]. Furthermore pre-transplant ATG is effective in reducing the burden of GVHD associated with the use of mobilized blood stem cells [64]. An adequately sized controlled trial from Canada has recently demonstrated that marrows from G-CSF-treated donors lead to similar acute or chronic GVHD compared to mobilized blood stem cells [65]. Therefore, it remains speculative

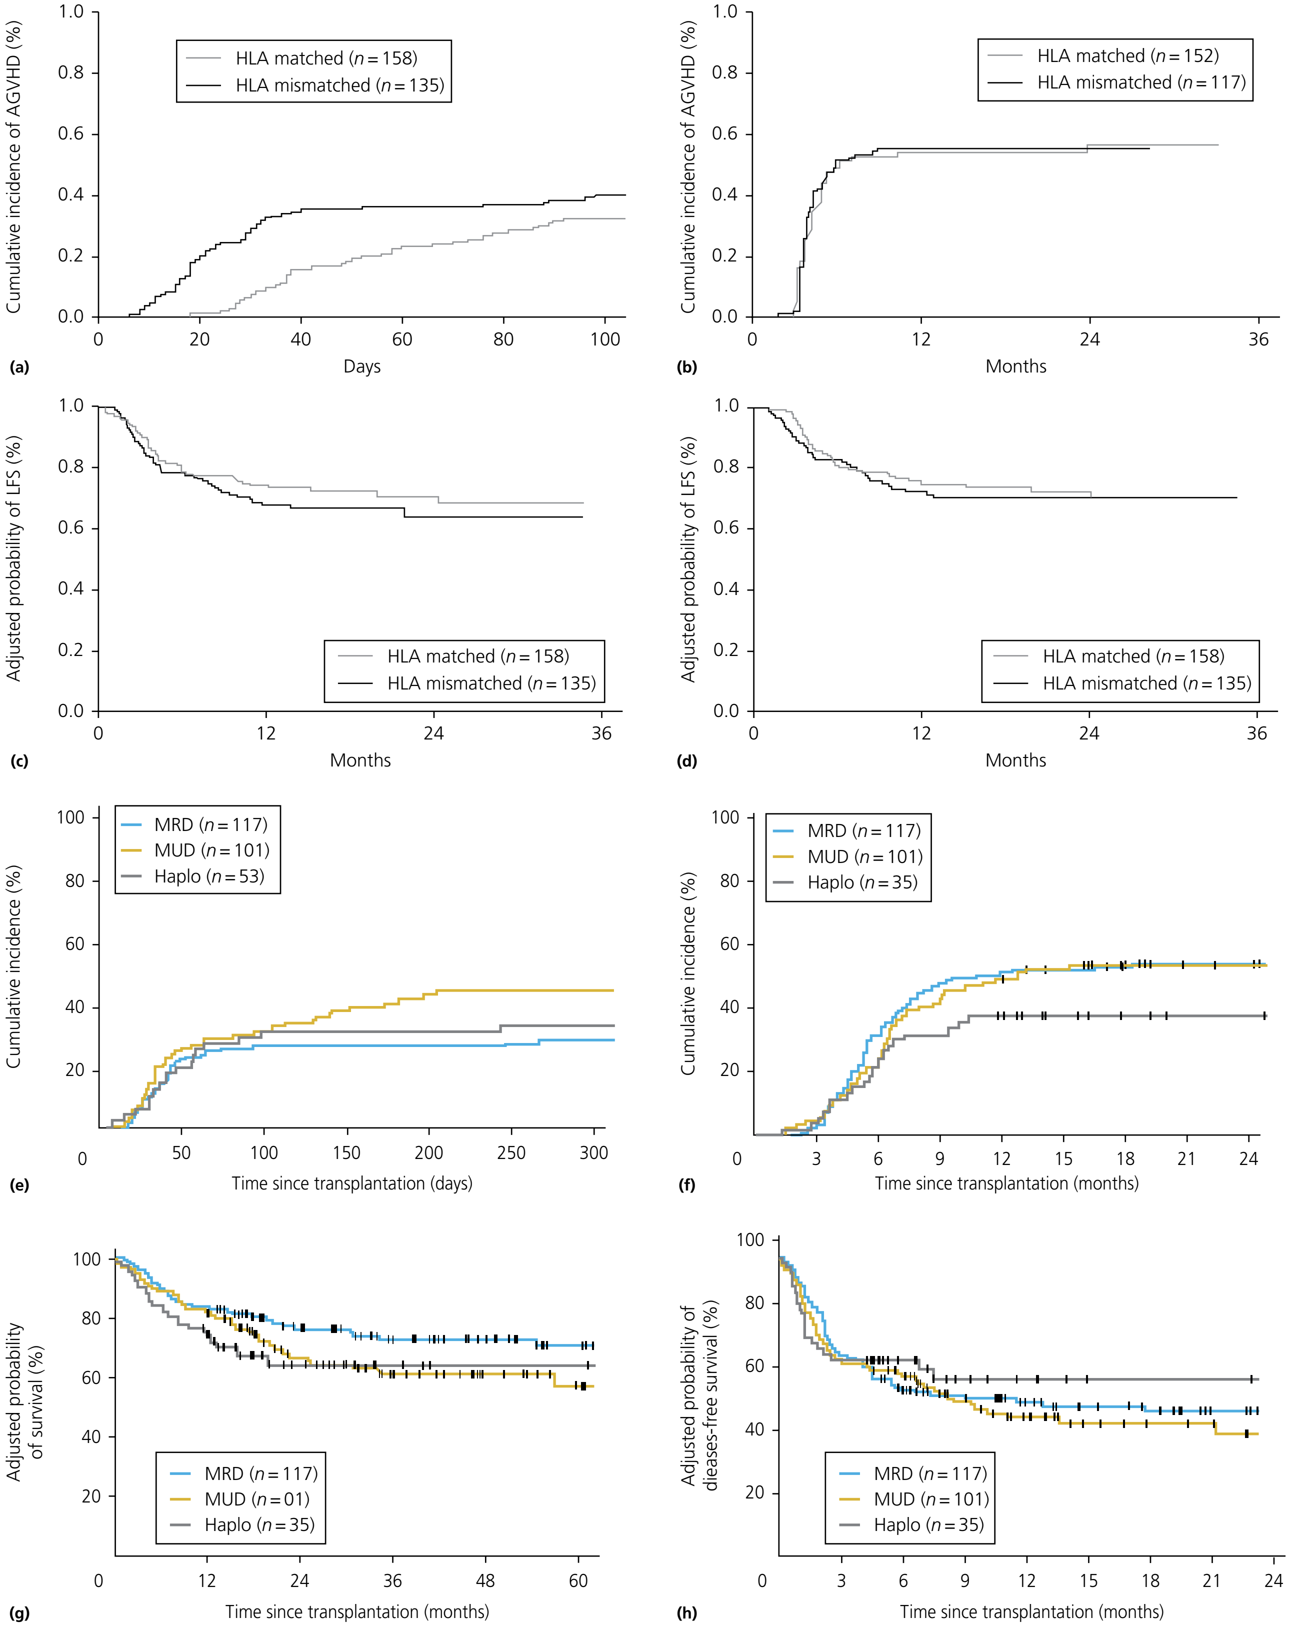

Figure 44.5 Effect of novel GVHD prevention regimens on outcomes. (a) Pre-transplantation ATG and post-transplantation mycophenolate mofetil: cumulative incidence of acute GVHD (A), chronic GVHD (B), disease-free survival (C), and survival (D) after HLA-identical sibling or HLA-mismatched related transplantations with (p = 0.13 and p = 0.97, respectively). Source: Lu et al. 2006 [56]. (b) Post-transplantation cyclophosphamide: cumulative incidence of acute GVHD (E), chronic GVHD (F), survival (G), and disease-free survival (H) by donor type. whether the addition of bone marrow cells to a mobilized blood stem cell graft helps in securing engraftment while ameliorating GVHD.

Mycophenolate mofetil was almost as effective as methotrexate in the prevention of GVHD in HLA-matched HCT in controlled trials, when used in combination with calcineurin inhibitors [66,67]. Since mycophenolate mofetil and methotrexate have distinct mechanism of action, it is likely that their combination is additive in preventing GVHD. Controlled trial evidence for this interaction, however, is lacking. These data suggest that G-CSF mobilized stem cells contribute to overcoming the risk of graft rejection, while the addition of pre-transplant ATG and post-transplant mycophenolate mofetil to standard regimens may offset the risks of GVHD associated with donor HLA-mismatching.

Post-transplantation, high-dose CY

Data from experimental animals indicate that post-transplantation CY depletes at least in part alloreactive effector T cells, while sparing regulatory T cells that are important for induction of transplantation tolerance [68]. Two independent clinical trials from Johns Hopkins and Seattle evaluated the safety and efficacy of high-dose, post-transplantation CY to prevent graft rejection and GVHD after outpatient reduced-intensity conditioning and T-cell-replete bone marrow transplantation from partially HLA-mismatched related donors [69]. Patients with advanced hematologic malignancies ($n = 87$) or paroxysmal nocturnal hemoglobinuria ($n = 1$) were treated with a reduced-intensity regimen of fludarabine 150 mg/m^2, CY 29 mg/kg, and TBI 200 cGy before marrow transplant, and post-transplantation CY (50 or 100 mg/kg), tacrolimus, and mycophenolate mofetil after the transplant [69,70]. Graft failure occurred in 15 (18%) of the 84 evaluable patients, and was fatal in two. The cumulative incidences of grade II–IV and grade III–IV acute GVHD by day 200 were 35% and 10%, respectively, and that of chronic GVHD at 1 year was 22%. The cumulative incidences of non-relapse mortality and relapse at 1 year were 19% and 50%, respectively. Overall and event-free survivals at 2 years after transplantation were 35% and 24%, respectively. These data strongly suggest that post-transplantation CY can decrease the risk of graft rejection, GVHD, and mortality associated with donor HLA disparity. A prospective, multicenter trial by the US Blood and Marrow Transplant Clinical Trials Network confirmed this observation [71].

Engraftment and GVHD are enhanced by more intense pre-transplantation conditioning therapy that ablates recipient immunity responsible for graft resistance. At least four independent teams have reported that post-transplantation CY is effective in controlling the risk of acute and chronic GVHD after myeloablative regimens [72–75]. In each of these trials, CY was followed by maintenance immunosuppression with tacrolimus and mycophenolate mofetil. There is theoretical concern about the risk of myelodysplasia secondary to hematopoietic stem cell exposure to the alkylating effects of CY, and to offset such a risk it is feasible to administer selected donor CD34 cells after CY therapy [75]. An analysis of post-transplantation CY from Northside Hospital in Atlanta, USA, found increased acute but not chronic GVHD and similar survival in patients treated with reduced-intensity or ablative regimens, and marrow grafts from HLA-mismatched related compared to HLA-matched related or unrelated donors (Figure 44.5) [12]. Prospective comparison of post-transplantation CY and ex vivo or in vivo T-cell depletion using T-cell-specific antibodies has not yet been performed in HLA-mismatched transplantations.

Graft failure with T-cell-replete marrow

Diagnosis of graft failure and second transplants

Primary graft failure is likely to occur if severe granulocytopenia persists for 21 days after transplantation of marrow or PBPCs, but secondary graft failure may also occur after initial engraftment (see Chapter 77) [10]. Studies of chimerism (see Chapter 24) are necessary to assess the presence of donor cells. Functional studies in patients with graft failure have demonstrated that residual host T lymphocytes are cytotoxic against donor alloantigens, and the patient's serum may be active in the antibody-dependent cell-mediated cytotoxicity test against donor cells [76,77]. These findings have indicated that alloimmune-mediated rejection is a mechanism for graft failure after HCT from HLA-incompatible donors. If a high-dose conditioning regimen is administered, either primary or secondary graft failure is usually associated with persistent aplasia. In certain patients, recovery of autologous myeloid cells can occur, especially if the patient is pretreated with reduced-intensity conditioning regimens and administered granulocyte–macrophage colony-stimulating factor (GM-CSF) or granulocyte colony-stimulating factor (G-CSF) after graft failure [78]. If there is no recovery of myeloid function despite growth factor therapy, a second transplant from the same or a different donor can be attempted, but the success of second transplants has been limited [79].

Risk of HLA disparity

The relevance of HLA compatibility to sustained engraftment was first analyzed in 269 patients with hematologic neoplasms who underwent T-replete marrow transplantation from a family member who shared one HLA haplotype with the patient, but differed to a variable degree for the HLA-A, -B, and -DR antigens of the unshared haplotype [10]. All patients were treated with cyclophosphamide (CY) and total body irradiation (TBI). The incidence of graft failure was 12.3% among recipients of marrow from an HLA partially matched donor compared with 2.0% among recipients of marrow from an HLA-matched sibling ($p = 0.0001$) (Table 44.2). The incidence of graft failure correlated with the degree of HLA incompatibility in the host-versus-graft direction.

Recipient HLA homozygosity

When the recipient is homozygous at a mismatched HLA locus, the degree of HLA disparity is greater in the direction of rejection than in the direction of GVHD (Table 44.1). Transplants in recipients homozygous at one or more mismatched loci had a significantly higher incidence of graft failure than transplants in heterozygous recipients. Graft failure after a transplant mismatched for one or more HLA loci occurred in 11 of 76 (15%) homozygous recipients compared with 22 of 350 (6%) heterozygous recipients. The effect of the vector of incompatibility on graft failure was significant in a multivariable analysis ($p = 0.005$). The association between recipient

Table 44.2 Effect of HLA incompatibility on marrow graft failure

	HLA-non-identical donor ($n = 269$) number of patients (%)	HLAgenotype-identical donor ($n = 930$) number of patients (%)	*p* value
Failure of engraftment	23 (8.5%)	15 (1.6%)	<0.0001
Late graft failure	10 (4.1%)	4 (0.4%)	<0.0001
All failures	33 (12.3%)	19 (2.0%)	<0.0001

HLA, human leukocyte antigen.

homozygosity for the mismatched locus and increased graft failure has been confirmed in a subsequent study of HLA-mismatched unrelated donor transplants [25]. These results are consistent with the concept that the graft-versus-host reaction protects from graft failure. Presumably, the graft-versus-host reaction is directed against residual immune cells of the recipient that are responsible for graft failure. In cases where the degree of disparity in the donor exceeds the degree of disparity in the host, the graft-versus-host reaction is less and the risk of graft failure is increased.

Immune competence

The risk of graft failure is low in patients who are immunodeficient by virtue of a congenital disorder or as the result of prior cytotoxic or immunosuppressive therapy provided as treatment for the underlying disease. Most patients with severe combined immunodeficiency lacking both T and NK cells have been engrafted with HLA-incompatible HCT despite receiving neither pre-transplant conditioning nor post-transplant immunosuppression [80]. Patients with leukocyte adhesion deficiency (see Chapter 73), a congenital defect resulting in failure to express the leukointegrin β2 chain on white cells including T and NK cells, demonstrate low resistance to engraftment with T-depleted transplants from HLA-incompatible donors [81]. Thus, β2 leukointegrins have a critical role in the rejection of HLA-incompatible HCTs. Patients with chronic myeloid leukemia (CML) have a higher risk of graft failure than patients with acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL). The incidence of graft failure was examined in non-T-depleted marrow grafts from HLA partially matched relatives in patients treated with the same conditioning regimen of CY (120 mg/kg) plus hyperfractionated TBI (1320–1440 cGy) followed by post-transplant immunosuppression with cyclosporine (CSP) and a short course of methotrexate (MTX). Graft failure occurred in 11 of 84 (13%) patients with CML compared with five of 133 (4%) patients with other diagnoses (odds ratio = 3.5; 95% CI, range 1.1–10.5; multivariate $p = 0.03$) [44]. Patients with acute leukemia may be at lower risk for graft failure because of the immunodeficiency induced by repeated treatment with chemotherapy agents [82].

Conditioning regimen intensity

Pre-transplant conditioning with CY (120 mg/kg over 2 days) and TBI (920–1575 cGy) allowed engraftment in 88% of 269 patients transplanted from HLA partially matched relatives [10]. Thus, a high-dose conditioning that includes TBI is not uniformly effective in facilitating engraftment of HLA-incompatible marrow or PBPC grafts. Increasing the immune-suppressive potency of the pre-transplant conditioning regimen can minimize the incidence of immune-mediated rejection. A more effective high-dose regimen containing TBI was developed for T-depleted transplants: CY was replaced by ATG, fludarabine, and thiotepa, agents that contributed immunosuppressive activity without additional toxicity (see later, under T-cell-depleted transplants) [83]. Pre-transplant immunosuppression with CY, fludarabine, and thiotepa was developed to facilitate engraftment of HLA-mismatched cord blood, and is very effective to facilitate engraftment after HLA-disparate related donor transplants [59,84]. Thalassemia patients are not only more immunocompetent than leukemia patients but are also sensitized to histocompatibility antigens by multiple blood cell transfusions. The addition of thiotepa to BU/CY decreased significantly the risk of graft failure in thalassemia patients transplanted from HLA partially compatible unrelated donors [85].

Graft cell dose

Cord blood transplantation provides the most convincing data demonstrating that low cell dose is a risk factor for graft failure after HLA-mismatched transplants [4,5]. Conversely, a controlled trial in unrelated donor transplantation formally demonstrated that PBPC lowers the risk of graft failure compared to marrow [63]. Protocols that use in vivo or ex vivo T-cell depletion have adopted PBPC to optimize engraftment and prevent graft failure [10,11].

Post-transplant immunosuppression

Post-transplant immunosuppression decreases the risk of graft failure. Patients transplanted from HLA partially matched donors had a graft failure rate of 5% when treated with CSP plus short-course MTX, but 9% when treated with MTX alone ($p = 0.03$) [44]. This observation is consistent with the report from the Center for International Blood and Marrow Transplant Research (CIBMTR) showing that, in T-depleted marrow transplants from HLA-identical sibling donors, the use of post-transplant immunosuppression with CSP plus MTX was associated with a lower risk of graft failure than CSP alone [86].

Immune reconstitution

After transplantation, new T cells are derived from donor hematopoietic stem cells (HSCs) following positive and negative selection within the host thymus. T lymphocytes recognize immunogenic peptides presented by self-HLA but not by mismatched allogeneic HLA molecules, a phenomenon defined as HLA restriction. Positive T-cell selection is facilitated by HLA molecules expressed on thymic epithelial cells, whereas negative selection is controlled predominantly by HLA molecules expressed on marrow-derived APC [87]. Thus, new T cells that are positively selected on thymic epithelium can optimally recognize antigen in the context of marrow-derived APCs in peripheral tissues only if there is sharing of HLA antigens between donor and recipient [88]. Mature T cells transplanted into an HLA-disparate recipient may not recognize antigens presented by host APCs, thereby failing to help immune reconstitution. These premises justify why donor and recipient matching for at least one HLA haplotype is the minimum requisite for donor selection.

Extrathymic pathways of immune reconstitution after transplantation are predominant in adults as thymus function begins to decline relatively early in life, usually before the age of 20 years. Therefore, T cells that repopulate adult transplant recipients are derived predominantly from the relatively small number of mature donor T cells infused with the hematopoietic cell inoculum [89]. Immunosuppressive regimens should be developed that are effective in preventing GVHD while sparing donor T cells that do not recognize host alloantigen but contribute to long-term immune reconstitution. Both acute and chronic GVHD also contribute to immunodeficiency. Because adult patients have very poor thymic function, T-cell-depletion has been associated with severe and prolonged postgrafting immunodeficiency [90]. Data on T-cell receptor excision circles as a marker for recent thymus emigrants has demonstrated that the human thymus continues to function at low levels until late in life, providing hope that effective treatment can be developed to restore immunity quickly in T-cell-deficient adults [91]. Initial data on interleukin-7 (IL-7) is promising for this application [92,93].

Graft-versus-leukemia effect

Relapse of leukemia after HLA-identical sibling transplants is less frequent in patients who develop clinically significant GVHD compared with syngeneic or allogeneic transplant recipients without GVHD (see Chapter 16). Patients with ALL after transplantation from HLA partially matched donors in whom GVHD developed also had a lower risk of relapse than patients without GVHD [8]. In one analysis, chronic but not acute GVHD was associated with a lower relapse rate in patients with AML or CML [8]. However, the probability of leukemic relapse in patients without clinically significant GVHD was the same whether the marrow donor was an HLA-identical sibling or an HLA partially matched relative. These data suggested that HLA disparity in absence of acute GVHD has no obvious antileukemic effect. Because recipients of one-HLA locus-incompatible transplants have a higher incidence of acute GVHD than recipients of HLA-identical sibling transplants, one would expect to see a lower incidence of leukemic relapse. A study from the CIBMTR comparing the outcome of 1222 HLA-identical sibling transplants to that of 238 transplants from one-HLA locus-incompatible donors failed to detect different rates of relapse [52]. The use of T-cell-replete grafts of G-CSF-mobilized PBPCs from one-HLA antigen-mismatched related or unrelated donors has been associated with a lower risk of post-transplant relapse in patients with CML [94]. The apparent increase in antitumor effect with PBPCs compared with marrow is likely related to the number of donor T cells transplanted [95].

Making a choice among stem cell sources

A large study from the CIBMTR compared the outcomes of marrow transplants from HLA-identical siblings, HLA partially matched related donors, and unrelated donors for treatment of leukemia [52]. The definition of donor and recipient histocompatibility was based exclusively on historical serologic data and not on cellular or DNA typing. The probability of leukemia-free survival for patients transplanted for early-stage leukemia, CML in chronic phase, AML or ALL in first remission is presented in Figure 44.4(b). A multivariable analysis of transplant-related mortality showed an increase in risk with the use of a one-HLA locus-mismatched relative compared with an HLA-identical sibling, and for the use of a two-HLA locus-incompatible relative compared with a one-HLA locus-incompatible relative. Results of matched unrelated donor transplants were similar to results of one-antigen-mismatched related donor transplants, while results for one-antigen-mismatched unrelated donor transplants were similar to results for two-antigen-mismatched related donor transplants [52]. Taken together, these data demonstrate that a limited degree of HLA disparity between donor and recipient can be tolerated with T-cell-replete marrow in transplants for hematologic malignancies, but a higher degree of donor HLA disparity reduces survival.

A subsequent CIBMTR study confirmed the original findings of similar survival after transplantation from one-locus incompatible related compared to unrelated donors that were well-matched using DNA typing technology [96]. Conversely, a report from the Japanese Marrow Donor Program showed inferior survival with one-locus-mismatch related donors compared to well-matched unrelated donors typed by high-resolution DNA typing technology [97]. The apparent discrepancy may be related to genetic heterogeneity between the predominantly Caucasian population in the CIBMTR report and the Japanese or the choice of transplant protocols that may offset the HLA effect.

A single-center study from Milwaukee compared transplantation outcomes in patients with hematologic malignancies who received marrow grafts from either HLA-matched unrelated, one-antigen-mismatched unrelated or highly mismatched family donors [98]. All patients received a standardized conditioning regimen and a uniform GVHD prophylaxis schedule – with the exception of mismatched related recipients, who received ATG as additional postgrafting immunosuppression. There was a higher probability of survival for matched unrelated transplants (58%) than either mismatched unrelated (34%; $p = 0.01$) or mismatched related transplants (21%; $p = 0.002$). This study supports the fact that patients lacking an HLA-matched family donor can be offered a matched unrelated donor, if available. Effective transplant protocols have challenged this conclusion by producing similar survival after transplantations from HLA-mismatched related donors, matched siblings or matched unrelated donors [10–12]. Only one prospective trial has been designed to address the effectiveness of transplantations from HLA-mismatched unrelated cord blood versus HLA-mismatched related donors for adult patients with hematologic malignancies, and it is ongoing in the United States within the Blood and Marrow Transplant Clinical Trials Network.

Transplantation of T-cell-depleted hematopoietic cell grafts

Risk of graft failure with T-cell-depleted marrow

Numerous clinical trials have demonstrated that extensive ex vivo depletion of T cells from the marrow graft without post-transplant immunosuppression prevents acute and chronic GVHD and associated morbidity (see Chapter 82). Unfortunately, marrow T-cell depletion is associated with an increased risk of graft failure that is proportional to the degree of donor HLA incompatibility. A study from the CIBMTR on transplantation from donors incompatible for two or three HLA-A, -B, and -DR antigens found an incidence of graft failure of 42% with T-cell-depleted marrow compared with 28% in non-T-cell-depleted marrow ($p < 0.03$) [9]. In a small series of patients with leukemia transplanted from a two- or three-HLA antigen-mismatched donor at Memorial Sloan Kettering Cancer Center, New York, the use of T-cell depletion was also associated with an incidence of graft failure approaching 50%. In contrast, T-cell-depleted marrow from parents incompatible for a full HLA haplotype engrafted almost all patients with severe combined immune deficiency [80].

In immune-competent hosts, resistance to engraftment is mediated primarily by host T lymphocytes [76]. We presume that with T-cell-depleted marrow grafts, the balance between competing host and donor T cells shifts in favor of the host, resulting in unopposed host-versus-graft reaction. In rodents, resistance to MHC-incompatible HCT can be overcome by adding BU, thiotepa, or anti-T-cell antibodies to the host-conditioning, or by increasing the number of donor T cells or hematopoietic cells in the donor graft [99]. In leukemia patients transplanted from HLA-mismatched donors, a regimen of TBI, CY, thiotepa, and ATG was inadequate for engraftment of T-cell-depleted marrow, but was adequate for engraftment of T-depleted PBPCs [10].

Partial marrow T-cell depletion

Since even a small number of T cells in the marrow inoculum can overcome allogeneic resistance, investigators have developed strategies for partial T-cell depletion. Removal of less than 2 logs T cells from the donor marrow requires, however, the administration of post-transplant immunosuppression for the prevention of GVHD. In 201 patients, conditioning comprised high doses of TBI, CY, cytarabine, and etoposide, while GVHD prophylaxis consisted of partial marrow T-cell depletion with either anti-CD3 murine monoclonal antibody OKT3 ($n = 143$) or T10B9 ($n = 58$), plus post-transplant immunosuppression with ATG, CSP, and glucocorticoids [100]. Engraftment occurred in 98% of patients, grade II–IV acute GVHD in 13%, and chronic GVHD in 15%. The 5-year transplant-related mortality, however, was 51% and was caused predominantly by opportunistic infections. The incidence of relapse was 31%, and the 5-year disease-free survival was 18%. Patient age greater than 15 years, active disease at transplant, donor age greater than 25 years, and a donor mismatched for three HLA-A, -B, and -DR antigens adversely affected outcome. This study demonstrated that partial T-cell depletion plus postgrafting immunosuppression can prevent GVHD after marrow transplantation from donors mismatched for one HLA haplotype, that the risk of graft failure is low, but that mortality from opportunistic infections is unacceptably high.

Hematopoietic cell dose and use of PBPCs

Preclinical studies

Animal models showed that high doses of T-cell-depleted marrow cells can overcome the MHC barrier without causing GVHD [99]. When purified HSCs were transplanted in irradiated mice, stable hematopoietic chimeras were generated in all cases, but 10–60 times the number of HSCs were required for the survival of mice transplanted across MHC disparities compared with no MHC disparities. Cell-dose escalation allowed full donor cell engraftment even in mice that had been presensitized by donor lymphocytes, in mice whose immune system had been partially reconstituted with the infusion of small numbers of host T cells before the allogeneic transplant, and in mice pretreated with sublethal doses of TBI low enough to spare recipient T lymphocytes. Human $CD34^+$ cells exhibited "veto" activity in vitro, that is, they neutralized allogeneic cytotoxic T-lymphocyte precursor cells directed against their antigens but not against a third party [101,102]. Early myeloid $CD33^+$ cells were also endowed with marked veto activity, which is not found in late myeloid cells expressing CD14 or CD11b. Therefore, soon after transplantation, infused $CD34^+$ cells and their $CD33^+$ progeny might inhibit residual antidonor cytotoxic T-lymphocyte precursors from the recipients through deletion mediated by tumor necrosis factor-alpha [103].

Transplant studies: the benchmark "Perugia" protocol

The hypothesis that escalation of the hematopoietic cell dose can facilitate engraftment of T-cell-depleted, HLA-mismatched transplants was first tested in patients with advanced leukemia. In 1993, the Perugia Bone Marrow Transplant Center developed a transplant protocol using the combination of G-CSF-mobilized T-depleted PBPCs and T-cell-depleted marrow cells for transplantation from HLA-mismatched relatives [10]. Donor and recipients were incompatible for two or three HLA-A, -B, and -DR antigens of the unshared haplotype. More than 3 log depletion was achieved and the T-cell content in the graft was a median of $1–2 \times 10^5$/kg recipient body weight, and $CD34^+$ cells showed a median of 10×10^6/kg recipient body weight. The average dose of GM-CFU was seven- to 10-fold greater in the combined product than in marrow alone. Conditioning included TBI (8 Gy at an instantaneous dose rate of 16 cGy per minute with the lungs shielded to receive 7 Gy), thiotepa (10 mg/kg over 2 days), CY (120 mg/kg over 2 days), and rabbit ATG (25 mg/kg over 5 days). All patients received G-CSF after transplantation until engraftment and no planned post-transplant immunosuppression. Sixteen of 17 patients with advanced leukemia achieved primary engraftment. Acute GVHD grade II–IV occurred in one patient, and there were no cases of chronic GVHD. Two patients relapsed, and nine died of transplant-related complications, which were mainly infections. Six of 17 patients survive [10].

After the first pilot study of T-cell-depleted PBPCs plus marrow, the Perugia team focused on a graft containing only PBPCs and on optimizing the graft-processing by means of automated positive $CD34^+$ cell selection. This approach ensured a median of 4.5 log T-cell depletion and a 3.2 log B-cell depletion, which helps prevent Epstein–Barr virus-associated lymphoproliferative disorders [104]. To minimize the extrahematologic toxicity of the conditioning regimen, fludarabine (40 mg/m^2/day for 5 days) replaced CY, based on data from a murine model where fludarabine/TBI provided similar immunosuppression to TBI/CY [105]. In addition, the dose of total lung irradiation was decreased from 7 to 4 Gy. The modified protocol was tested in 43 adult patients with high-risk acute leukemia. Primary sustained engraftment was achieved in 41 of 43 (95%) patients. Grade II–IV GVHD did not occur. The 2-year disease-free survival was 36% for 20 patients with AML, and 17% for 23 patients with ALL ($p = 0.05$), and all survivors recovered a normal performance status [46]. In a subsequent confirmatory series, primary engraftment was achieved in 94 of 101 patients, and six more engrafted after a second transplantation. Acute GVHD developed in eight patients, and chronic GVHD in five. Thirty-eight patients died of causes other than leukemia. Relapse occurred in nine of 66 patients receiving transplantation in remission, and in 17 of 38 receiving transplantation in relapse. Event-free survival at 1 year was 48% and 46%, respectively, for the 42 AML and 24 ALL patients receiving transplantation in remission, and 4% for the 38 patients with AML or ALL receiving transplantation in relapse [106].

An analysis of 255 high-risk acute leukemia patients treated in Perugia over almost 20 years showed a relapse rate of 18% with AML and 30% with ALL in any complete remission (CR) [107]. The intensely myeloablative conditioning regimen likely contributed to leukemia control. In the absence of post-transplant immunosuppression, the few T cells in the graft may have mounted a subclinical graft-versus-leukemia effect (GVLE), and donor-versus-recipient NK alloreactivity, a biologic effect unique to mismatched transplant, helped prevent relapse of AML. The cumulative-incidence of non-relapse mortality was 0.36 (95% CI, 0.29–0.53) for 145 patients in any CR at transplant and 0.58 (95% CI, 0.40–0.65) for 110 patients transplanted in relapse. Event-free survival (EFS) was 43% with AML and 30% with ALL in any CR, with no events occurring between 2 and 17 years of follow-up. Patients with advanced AML had a noticeable 18% EFS. All long-term survivors enjoy an excellent quality of life with no cGVHD.

A European Group for Blood and Marrow Transplantation retrospective study, analyzed the outcome of haploidentical transplantation in several European centers and reported similar results with a 48% one-year EFS for AML patients in first CR [108]. Encouraging results were also demonstrated in pediatric patients. A European multicenter analysis of 127 children with high-risk ALL reported a 5-year disease-free survival (DFS) of 27% for patients in CR [109]. A multivariate analysis detected a trend toward a center-related effect with better DFS in larger centers (39% vs. 15%). An improved outcome with less relapse was also described for patients receiving a higher $CD34^+$ cell dose.

These clinical trials demonstrated that a highly immune-suppressive conditioning regimen of TBI, fludarabine, thiotepa, and ATG combined with positively CD34-selected PBPC cells can overcome the engraftment barriers across HLA disparities in leukemia patients. In addition, $CD3^+$ cell doses up to 2×10^4/kg do not cause severe GVHD if ATG is administered as part of the conditioning regimen.

Effective GVHD prevention by CD34 positive selection hinders the antileukemia effects mediated by T cells against histocompatibility antigens on recipient leukemia [86], but donor NK-cell alloreactivity against the recipient contributed to control post-transplant relapse in AML patients (see the section on NK alloreactivity later).

T-cell negative selection from PBPCs and reduced-intensity conditioning

Handgretinger and collaborators modified the Perugia protocol by substituting OKT3 for ATG, and shifting from positive CD34^{+} cell selection to negative selection through the use of CD3- and CD19-coated CliniMACS microbeads, so as to infuse both CD34^{+} and CD34^{-} cells, including CD8^{+} T cells, NK cells, and other accessory cells in addition to hematopoietic precursor cells [110]. In contrast to the frequently used polyclonal ATG, OKT-3 spares incoming engraftment facilitating cells such as NK-cells. In children with leukemia or lymphoma, Lang et al. [111] compared positive HSC selection with CD34- ($n = 39$) or CD133-coated magnetic microbeads ($n = 14$) to T- and B-cell depletion using CD3- and CD19-coated microbeads ($n = 11$). Primary engraftment was 85% after CD34-positive selection, 72% after CD133-positive selection, and 91% after CD3/CD19-negative selection. The incidence of grade II–IV GVHD was similar after CD34- or CD133-positive selection (3% and 7%, respectively), but increased to 27% after CD3/CD19-depletion. Despite the rise in GVHD, the investigators reported a lower than 10% incidence of fatal viral infections, suggesting that rapid CD3^{+} cell recovery had occurred. Graft processing by negatively selecting T cells that express an alpha/beta T-cell receptor could exploit the principle that gamma/delta T cells do not cause GVHD and may have antileukemia effects [112]. It remains unclear whether CD3 or T-cell receptor α/β plus CD19-negative selection provides any advantage over positive CD34-selection, or whether OKT3 is as effective as ATG.

To reduce toxicity, Bethge et al. designed a conditioning regimen consisting solely of chemotherapy: fludarabine (150–200 mg/m^2), thiotepa (10 mg/kg), melphalan (120 mg/m^2), and OKT3 (5 mg/day, from day −5 to day +14) and no post-transplant immunosuppression [113]. Engraftment was prompt, with full donor chimerism after 2–4 weeks in all patients. The incidence of grade II–IV GVHD was 48%. In the first 100 days, six of 29 (20%) patients died of treatment-related complications. A prospective multicenter phase II study of haploidentical HSC transplantation using CD3/CD19-depleted grafts after reduced-intensity conditioning with fludarabine, thiotepa, melphalan and OKT3 extended encouraging results to adults, median age 46 years (range, 19–65) [114]. In addition to chemotherapy the anti-CD3 monoclonal antibody OKT3 was used in order to deplete remaining host-T-cells, avoiding graft rejection. Only 30 of the 61 patients were in complete remission. Grafts contained a median of 7.0×10^6 (range, 3.2–22) CD34^{+} cells/kg, 4.2×10^4 (range, 0.6–44) CD3^{+} T cells/kg and 2.7×10^7 (range, 0.00–37.3) CD56^{+} cells/kg. Engraftment was rapid with median of 12 (range, 9–50) days to >500 granulocytes/μL and 11 (range, 7–38) days to >20,000 platelets/μL. Incidence of grade III–V acute and chronic GVHD was 46% and 18%, respectively. The authors concluded that with this regimen doses $<5 \times 10^4$ CD3^{+} cells/kg seem safe even without GVHD prophylaxis, doses of $>5 \times 10^4$ CD3^{+} cells/kg require GVHD-prophylaxis such as MMF. Doses $>15 \times 10^4$ CD3^{+} cells/kg should be avoided. Non-relapse-mortality on day 100 was 23%, and 42% at 2 years. Cumulative incidence of relapse/progression at 2 years was 31%. The Kaplan–Meier estimates of EFS were 34% at 1 year and 25% at 2 years, and the survival estimates were 41% at 1 year and 28% at 2 years. Blood T-cells were a median of 191 (range, 38–799) cells/μL on day 100, and the subset of naïve T cells were slower to repopulate compared to memory T cells with a median of 28 (range 0–152) CD4^{+}CD45RA^{+} versus 79 (range 14–310) CD4^{+}CD45R0^{+} cells/μL at days 100 and 166 (range 21–2396) versus 237 (range 46–252) at 400 days after transplantation. T-cell repertoire was skewed with oligoclonal T-cell expansion to day 100 and tended to normalize after day 200. DLI was used in 24 patients for relapse or mixed chimerism and a faster recovery in T- and NK cells occurred in six of the patients. Although this approach demonstrated that megadoses of stem cells higher than 10×10^6/kg and full myeloablative conditioning were not required for successful engraftment in HCT from haploidentical donors, it was complicated with higher relapse rates, possibly because of reduced intensity of the conditioning and persistently delayed immune reconstitution.

Studies using conventional high-dose conditioning regimens

In Japan, a transplant trial of CD34^{+} cells selected with the Isolex device (Miltenyi Biotec GmbH, Bergisch Gladbach, Germany) enrolled 135 children, 64 of whom received two-HLA locus-mismatched grafts, and 43 three-locus-mismatched grafts [115]. Median CD34^{+} cell doses were 3.2×10^6/kg for patients receiving marrow only, 5.5×10^6/kg for those receiving PBPCs only, and 4.9×10^6/kg for those receiving marrow and PBPCs, and median T-cell doses were 6.0, 9.4, and 12.1×10^4/kg, respectively. The conditioning regimens before HCT included TBI in 77% of the cases and ATG in 52%; therefore they were in general less intense and immunosuppressive than those developed in Perugia. Patients needed post-transplant immunosuppression to prevent GVHD. Graft failure occurred in 13% of patients with hematologic malignancies, and 40% of patients with non-malignant disease. The incidence of GVHD was 10% when ATG was included in the conditioning and 27% when it was not included. Disease-free survival at 5 years was 39% in standard-risk patients and 5% in high-risk patients. These results confirm that CD34^{+} PBPCs do not ensure consistent engraftment of HLA-mismatched transplants unless an optimized conditioning regimen is administered, and that GVHD prevention requires postgrafting immune suppression if T-cell depletion is suboptimal.

Harnessing immunity to infections and leukemia

Several mechanisms are responsible for patient immunodeficiency after transplantation of T-cell-depleted hematopoietic cells from HLA-incompatible donors. In adults, early immune recovery stems from the expansion of mature T cells in the graft. However, in HLA-mismatched transplants with T-cell-depleted grafts, the number of T cells in the graft must be sufficiently low to prevent GVHD, and anti-T-cell antibodies administered in the conditioning regimen further deplete the few transplanted T cells. Intense conditioning regimens induce tissue damage that prevents T-cell homing to peripheral lymphoid tissues, where the generation and maintenance of T-cell memory take place [116,117]. Administration of G-CSF after transplantation is immunosuppressive as it blocks IL-12 production by APCs and decreases T-cell responses to pathogens in vitro and in vivo after transplantation [118]. Since the administration of G-CSF after transplantation was omitted in the Perugia trials, engraftment rates have remained unchanged, and recovery rates of immune parameters, including APC production of IL-12, have improved [118].

Several strategies are under investigation to hasten post-transplant immune recovery and decrease mortality from opportunistic infections without causing GVHD. Reinfusion of non-alloreactive T cells into patients previously transplanted with T-cell-depleted grafts from HLA-mismatched donors may lead to immune reconstitution without GVHD. Such approaches involve the co-incubation of donor T cells with recipient APCs in the presence of agents that can selectively eliminate or inactivate host-reactive T cells. In two studies, donor T cells were exposed ex vivo to recipient alloantigen and treated with an immunotoxin specific for the IL-2 receptor alpha chain [119,120]. This approach was effective in selectively eliminating alloreactive T cells without eliminating T cells reactive to third-party antigens. Based on preclinical data that antigen presentation in the absence of CD28 co-stimulation induces a state of T-cell unresponsiveness, one clinical trial employed host APCs and soluble cytotoxic T-lymphocyte antigen-4 immunoglobulin (Ig) to present host alloantigen to donor T cells while blocking the CD28 co-stimulatory pathways. This approach resulted in ex vivo donor T-cell unresponsiveness to the HLA-mismatched cells of the recipient [121]. The latter approach appears to have the potential to facilitate engraftment and perhaps immune reconstitution, but does not appear to eliminate GVHD.

To hasten reconstitutition of pathogen-specific immunity, Perruccio et al. generated T-cell clones specific for *Aspergillus* or cytomegalovirus (CMV) antigens, screened them for cross-reactivity against recipient alloantigens, and infused the non-alloreactive clones soon after HCT [122]. The maximum safe dose (1 million $CD3^+$ cells/kg recipient body weight) appeared clinically effective and did not cause GVHD. CMV reactivation and *Aspergillus* galactomannan antigenemia disappeared over time, while the frequencies of anti-*Aspergillus*- and anti-CMV-specific T-cell clones increased. Pathogen-specific T cells persisted over time, did not cause GVHD, and were associated with control of *Aspergillus* and CMV antigenemia and infectious mortality. In another study, CMV-specific T cells were generated by ex vivo stimulation with CMV pp65 and infused to control refractory CMV viremia or disease after HLA-matched unrelated donor or haploidentical HCT [123]. Similar approaches were used to prevent or control adenovirus or Epstein–Barr virus infections [124–126]. Although efficacious such approaches are time consuming and labor intensive and thus not broadly applicable.

For adoptive transfer of T cells with a wide T-cell receptor repertoire, polyclonal donor T cells were engineered to express suicide genes, for example the herpes simplex thymidine kinase (HSV-TK) gene, to guarantee engineered cell lysis if they triggered GVHD [127,128]. To date, 128 patients were treated with TK-engineered T cells in several phase I or II clinical trials, and follow-up of more than 228 persons/year has been accumulated [129]. No adverse event related to gene transfer has been observed [129]. Most of the patients who received TK-engineered T-cell add-back after haplotype mismatched HCT obtained a rapid and broad immune reconstitution, protective against pathogens and apparently benefited from a low rate of infection-related mortality. Notably, in clinical trial "TK007," only patients with TK-engineered T-cell engraftment progressed to full-term immune reconstitution, whereas in the absence of TK-engineered T cells, the immune recovery was dramatically slow, and similar to that reported after TCD transplants. Although TK-engineered T-cell engraftment appeared necessary and sufficient to promote a robust T-cell recovery, the immune reconstitution was progressively enriched by T lymphocytes negative for transgene expression and retroviral integration. Starting from these observations, Vago et al. recently reported that donor-derived transgene-negative T cells, observed in TK007, were enriched for recent thymic emigrants, denoting their de novo generation in the host thymus [130]. These data indicate that immune reconstitution after TK-cell infusion is supported by a thymic-dependent pathway and results in the maturation and differentiation of donor hematopoietic precursors in the recipient thymus. The low incidence of GVHD observed in the absence of any pharmacologic immunosuppressive treatment, suggest that the high numbers of T cells circulating in these patients had achieved central tolerance in the patient thymus, with negative selection of host-reactive cells. This was also confirmed by the fact that the activation of the suicide gene machinery, sufficient to control GVHD, did not affect immune reconstitution [130]. Di Stasi et al. devised an inducible T-cell safety switch based on the fusion of human caspase 9 to a modified human FK-binding protein, allowing conditional dimerization and cell suicide following administration of the small molecule dimerizing drug AP1903 [131]. Five leukemia patients were transplanted with HLA-haploidentical, CD34-selected hematopoietic stem cells followed by infusion of the genetically modified T cells. Four patients developed GVHD and were treated with AP1903; 90% of the modified T cells were eliminated within 30 minutes and the GVHD was terminated without recurrence.

Photodepletion using dibromorhodamine (TH9402) in a mixed lymphocyte reaction efficiently eliminates alloreactive donor T lymphocytes against the recipient, as it affords a thousand-fold decrease in the frequency of alloreactive T cells [132–134]. In a phase I clinical trial, Grade II acute GVHD developed in 4/19 patients and extensive chronic GVHD developed in five. Immunologic reconstitution was dose-dependent as infection and non-relapse mortality rates improved with the highest T cell doses [135].

Naturally occurring regulatory T cells (Treg) are a thymic-derived $CD4^+$ cells subpopulation which constitutively expresses the IL-2 receptor (CD25). They play a crucial role in the control of autoimmune processes in mice and humans. Like all other T cell-receptor alpha/beta expressing T lymphocytes, Tregs are antigen specific. Various animal models of mismatched HCT have shown that priming and robust expansion of alloantigen-specific Tregs occur in the peripheral lymphoid organs. These cells act in an alloantigen-specific manner during their effector phase in vivo thus controlling activation and expansion of alloreactive donor T lymphocytes via interaction with APCs at priming sites. Infusion of naturally occurring Tregs or ex vivo expanded Tregs, followed by conventional T lymphocytes (Tcons), prevents GVHD and favors immune reconstitution [136–139]. These insights from animal models prompted the Perugia group to evaluate the impact of post-transplant adoptive immunotherapy with freshly isolated donor Tregs and Tcons in the clinical setting of mismatched transplantation. Twenty-eight leukemia patients were conditioned with 8 Gy TBI, fludarabine, thiotepa, and CY. On day −4, 2×10^6/kg freshly isolated donor Tregs were infused, followed 4 days later, by 1×10^6 Tcons and 10×10^6 highly purified $CD34^+$cells/kg. Full donor engraftment was achieved in 26/28 patients. With no post-transplant pharmacologic immunosuppression, grade II–IV GVHD occurred in two cases and 13/26 evaluable patients died from non-relapse causes, including eight from infection with or without GVHD. The pattern of post-transplantation immune reconstitution featured rapid recovery of T-cell subpopulations, development of a wide T-cell repertoire, and high frequencies of pathogen-specific $CD4^+$ and $CD8^+$ lymphocytes. Indeed, patients had significantly fewer CMV reactivation episodes; none died of CMV disease [140].

These studies demonstrated the naturally occurring Tregs that are harvested from healthy donors efficiently control the alloreactivity of large numbers of otherwise lethal, conventional T cells. Evidently, activation of alloantigen-specific Tregs occurs efficiently in vivo and is not associated with long-term inhibition of general immunity to pathogens. In a different approach by Brunstein et al. on 23 patients, double-unit unrelated cord blood cell transplantation was followed by infusion of 0.1–30.0 × 10^5/kg third-party unrelated cord blood Tregs, which were ex vivo expanded using anti-CD3/anti-CD28 antibody-coated Dynabeads [141]. The incidence of Grade II–IV aGVHD was lower than in historical controls (43% vs. 61%; $p = 0.05$), with no significant differences in relapse and infection rates.

A crucial point about adoptive immunotherapy with Tregs is whether a GVLE is maintained in high-risk patients with acute leukemia since FoxP3$^+$ Tregs can also suppress antitumor responses. Studies in human beings have highlighted the increase in number of FoxP3$^+$ Tregs in tumor tissues and draining lymph nodes in several types of cancer. In contrast, a mouse model of mismatched transplantation showed that early infusion of Tregs protected the animals from GVHD and did not abrogate Tcon-mediated GVL effect against A20 leukemia cell line [142].

To address the issue of leukemia relapse, a subsequent study investigated whether Treg–Tcon adoptive immunotherapy provided a Tcon-mediated GVLE in the absence of GVHD [143]. The conditioning regimen included total body TBI, thiotepa, and fludarabine. The first 25 patients also received cyclophosphamide, while 18 others received alemtuzumab or thymoglobulin 21 days before transplant to avoid interference with the subsequent Treg–Tcon. All patients received freshly isolated donor Tregs on day −4, followed by a megadose of purified CD34+ cells and Tcons on day 0. The 4-day interval between Treg and Tcon infusions was in accordance with animal data indicating that early Treg administration provided greatest protection against GVHD. No pharmacologic post-transplant GVHD prophylaxis was given. Thirty-three out of 43 patients had AML (18 in 1st CR, 15 in 2nd or subsequent remission), 10 had ALL (7 in 1st CR; 3 in 2nd or subsequent remission). All patients in 1st remission were at high risk of relapse. All patients received a full haplotype-mismatched graft, which included CD34$^+$ cells (mean 9.7 × 10^6/kg ± 3.1; mean contaminating T cells: 0.8 × 10^4/kg ± 0.4), Tregs (mean 2.5 × 10^6/kg ± 1) and Tcons (mean 1.1 × 10^6/kg ± 0.6). Forty-one of 43 patients achieved primary, sustained full-donor type engraftment and 6/41 (15%) patients developed grade II or greater acute GVHD. In two patients, GVHD required a short course of immunosuppression and one patient developed chronic GVHD. Twenty-three out of 41 patients are alive with a DFS probability of 0.56 at 18 months minimum follow-up. Overall, the cumulative incidence of non-relapse mortality was 0.40 which fell to 0.21 in 18 patients who received anti-T antibodies in the conditioning. At a median follow-up of 46 months (range 18–65 months), 2/41 evaluable patients have relapsed. In the Treg–Tcon cohort the cumulative incidence of relapse was significantly lower than in historical controls (0.05 vs. 0.21; $p = 0.03$). Multivariate analysis identified Treg–Tcon adoptive immunotherapy as the only predictive factor associated with a reduced risk of relapse (RR 0.06; 95% CI, 0.02–0.35; $p = 0.02$). Tregs did not impact upon post-transplant generation of donor versus recipient alloreactive NK cells. This report showed for the first time that Treg/Tcon infusion was associated with a surprisingly low incidence of leukemia relapse while it efficiently prevented GVHD. One may hypothesize that the infusion of high numbers of mature T lymphocytes in the absence of any post-transplant immunosuppression exerted the apparently strong antileukemia effect.

Role of NK cell alloreactivity in HLA-incompatible HCT

NK-cell activation is regulated by a balance between inhibitory and activating receptors (see Chapter 11). In humans, currently 16 inhibitory killer Ig-like receptors (KIR) genes and pseudogenes are known to codify for inhibitory and activating KIRs. Inhibitory KIRs recognize amino acids in the COOH-terminal portion of the MHC class I $\alpha1$ helix [144–146]. They possess two (KIR2D) or three (KIR3D) extracellular C2-type Ig-like domains and a long cytoplasmic tail (L) containing immunoreceptor tyrosine-based inhibition motifs, which recruit and activate SHP-1 and SHP-2 phosphatases for inhibitory signal transduction. KIR2DL1 recognizes HLA-C alleles characterized by a Lys80 residue (HLA-Cw4 and related; "Group 2" alleles). KIR2DL2 and KIR2DL3 (which are allele variants) recognize HLA-C with an Asn80 residue (HLA-Cw3 and related; "Group 1" alleles). KIR3DL1 is the receptor for HLA-B alleles sharing the Bw4 supertypic specificity (Tables 44.3 and 44.4).

Another type of human NK-cell inhibitory receptor involved in HLA recognition is CD94-NKG2A. It binds to the non-conventional class I molecule HLA-E [147]. Several HLA class I alleles provide signal sequence peptides that bind HLA-E and allow its expression at the cell surface. Consequently, it is expressed in every individual.

Inhibitory KIRs, CD94/NKG2A, and HLA-class I genes determine individual NK-cell repertoires during development [148,149]. As they are located on different chromosomes, receptors and ligands segregate independently in human pedigrees. The HLA class I genotype selects a self-tolerant repertoire by dictating which KIR and/or NKG2A receptor combinations are to be used as inhibitory receptors for self-HLA class I. Consequently, every functional NK cell in the mature repertoire expresses at least one inhibitory receptor for self-HLA: coexpression of two or more receptors is less frequent.

Since inhibitory KIRs recognize specific groups of HLA class I molecule, that is, HLA-C group 1, HLA-C group 2, or HLA-Bw4 alleles, NK cells with the potential to exert allogeneic reactions use KIRs as inhibitory receptors for self-HLA class I [150–155]. NK cells that express, as their only inhibitory receptor for self-HLA, a KIR for the class I group that is absent on allogeneic targets sense the missing expression of the self-class I KIR ligands and mediate alloreactions ("missing self" recognition) (Figure 44.6).

Most individuals can exert allogeneic reactions as they possess a full complement of inhibitory KIR genes. The KIR2DL2 and/or

Table 44.3 Human leukocyte antigen (HLA) class I specificity of the main inhibitory killer immunoglobulin-like receptors (KIRs) expressed by human natural killer (NK) cells

KIR genes*	Encoded protein	HLA specificity†
KIR2DL1	P58.1 receptor	HLA-C group 2 i.e., Cw2, Cw4, Cw5, Cw6 Sequence: Asn77, Lys80
KIR2DL2/3	P58.2 receptor	HLA-C group 1 i.e., Cw1, Cw3, Cw7, Cw8 Sequence: Ser77, Asn80
KIR3DL1	P70/NKB1 receptor	HLA-Bw4-associated i.e., B27

*KIR2D refers to receptor molecules with two immunoglobulin-like domains, whereas KIR3D refers to those displaying three immunoglobulin-like domains. Receptors having a long inhibitory cytoplasmic tail are designated as L (long), whereas those having a short activating tail are termed S (short).

†Two groups of HLA-C alleles can be distinguished on the basis of alternative amino acid sequence motif at position 77 and 80 of the $\alpha1$ helix.

Table 44.4 Human leukocyte antigen (HLA)-C group 1, HLA-C group 2 and HLA-Bw4 group alleles

Group 1 HLA-C alleles	Group 2 HLA-C alleles	HLA-Bw4 alleles
(Ser77, Asn80)	(Asn77, Lys80)	B5
Cw1		B13
	Cw2	B17
Cw3 (except C*0307, C*0310,[†] and C*0315)	C*0307 and C*0215	B27
	Cw4	B37
	Cw5	B38
	Cw6	B44
Cw7 (except C*0707 and C*0709)	C*0707 and C*0709	B47
Cw8		B49
Cw12[‡] (except C*1204 and C*1205)	C*1204 and C*1205	B51
Cw13		B52
Cw14 (except C*1404[§])		B53
C*1507	Cw15 (except C*1507)	B57
Cw16 (except C*1602)	C*1602	B58
	Cw17	B59
	Cw18	B63
		B77
		B*1513
		B*1516
		B*1517
		B*1523
		B*1524

Each serologically defined group includes all alleles except where noted.

[†] C*0310 (Ser77, Lys80) belongs to both HLA-C groups 1 and 2 [142]. C*0310 blocks natural killer (NK) cells expressing all HLA-C-specific receptors, but does not block clones expressing the Bw4 receptor.

[‡] C*1207 (Gly77, Asn80) cannot be assigned to either group based on its amino acid sequence, and still needs to be tested functionally.

[§] C*1404 (Asn77, Asn80) does not belong to either HLA-C group 1 or 2 and does not block NK cells expressing any HLA-C-specific receptor [142]. Expression of C*1404 in a patient behaves with respect to NK-cell recognition as if the patient does not express that HLA-C allele.

KIR2DL3 receptors for HLA-C group 1 are present in all; the KIR2DL1 receptor for HLA-C group 2 is found in 97% and the KIR3DL1 receptor for HLA-Bw4 alleles is found in approximately 90% of people [90,113,114]. Individuals expressing group 1 HLA-C alleles possess the KIR specific for group 1 HLA-C alleles (KIR2DL2 and/or KIR2DL3) and are alloreactive against cells from individuals who do not express group 1 HLA-C alleles. Individuals who express group 2 HLA-C alleles and possess the KIR specific for group 2 HLA-C alleles (KIR2DL1) exert NK alloreactions against cells from individuals who do not express group 2 HLA-C alleles. HLA-Bw4$^+$ individuals who also express the Bw4-specific KIR3DL1 receptor may have NK cells that are alloreactive against Bw4$^-$ cells. These KIR ligand mismatches occur often in donor–recipient pairs that are disparate for one HLA haplotype (Table 44.5).

When exerted in the donor-versus-recipient direction, NK cell alloreactivity emerged as a crucial factor in improving outcomes of haploidentical transplantation. The opportunity for NK cell alloreactivity reduced the risk of leukemia relapse, did not cause GVHD, and markedly improved event-free survival in a series of haploidentical transplants (57 patients with AML, 20 of whom were transplanted from NK-alloreactive donors) [154].

In an updated analysis [155], 112 patients with AML received HLA-incompatible HCT from NK-alloreactive ($n = 51$) or non-NK-alloreactive donors ($n = 61$). For patients in remission at the time of HCT, the cumulative incidence of relapse was significantly lower after transplantation from NK-alloreactive donors (3% vs. 47%; $p < 0.003$) (Figure 44.7), and this translated into an improved event-free survival (67% vs. 18%; $p = 0.02$) (Figure 44.7). For patients in relapse at the time of HCT, donor

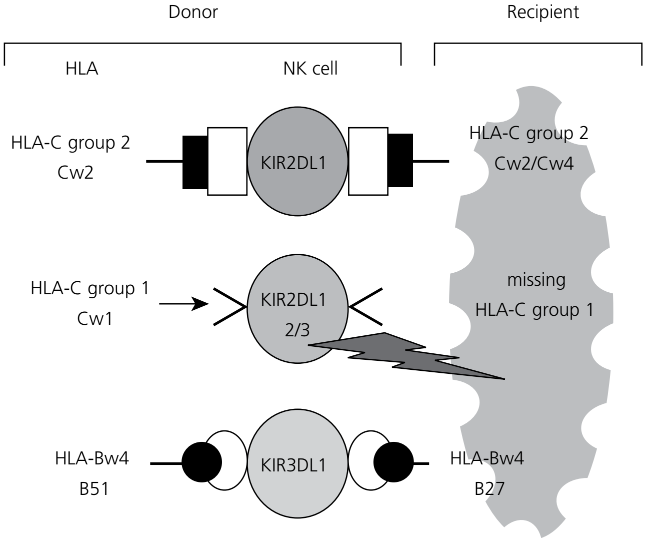

Figure 44.6 Donor-versus-recipient natural killer (NK) cell alloreactivity in human leukocyte antigen (HLA)-mismatched transplants. NK cell alloreactions are generated between donors and recipients who are killer immunoglobulin-like receptor (KIR) ligand-mismatched in the graft-versus-host direction. In these circumstances, donor NK cells expressing, as their only inhibitory receptor for self-HLA, a KIR for the class I group that is absent in the recipient sense the missing expression of the self-class I ligand on allogeneic targets and mediate alloreactions. This figure illustrates the example of a donor–recipient pair with a combination of mismatched HLA-C antigens, resulting in donor NK cell alloreactivity against recipient targets. The top donor NK cell expresses KIR2DL2/3 and is blocked by HLA-C group 1 antigens Cw1 on donor cells and Cw8 on recipient cells. The bottom donor NK cell expresses KIR3DLI that is blocked by Bw4 on both recipient and donor cells. The middle donor NK cell expresses KIR2DL1 that is blocked by donor (self)-HLA-Cw2 (an HLA-C group 2 antigen), but not by the recipient HLA-Cw3 (an HLA-C group 1 antigen). Consequently, this NK cell is alloreactive and lyses the recipient's cells (lightning bolt).

Table 44.5 Donor–recipient human leukocyte antigen (HLA) class I combinations associated with natural killer (NK) cell alloreactivity in the graft-versus-host direction

Recipient HLA type	HLA type of NK-alloreactive donor*
Group 1 HLA-C, Group 2 HLA-C, HLA-Bw4	No NK-alloreactive donor
Group 1 HLA-C, Group 2 HLA-C	HLA-Bw4
Group 1 HLA-C, HLA-Bw4	Group 2 HLA-C
Group 2 HLA-C, HLA-Bw4	Group 1 HLA-C
Group 1 HLA-C	Group 2 HLA-C and/or HLA-Bw4
Group 2 HLA-C	Group 1 HLA-C and/or HLA-Bw4

*Recipients who express class I alleles belonging to the three major class I groups (HLA-C group 1, HLA-C group 2, and HLA-Bw4 alleles) will block all NK cells from every donor. Donors may exert donor-versus-recipient NK cell alloreactivity when HLA-C and HLA-B typing shows KIR-ligand mismatches in the graft-versus-host direction, that is, the recipient does not possess one HLA-C allele group (C1 or C2) and/or the HLA-Bw4 group that are present in the donor. In the donor's HLA typing, the alleles listed are associated with the potential to exert NK cell alloreactions against the specific HLA type of the recipient, whatever other alleles may be present.

The HLA-C group 1 receptor genes (KIR2DL2 and/or KIR2DL3) are present in 100% of individuals. High-frequency alloreactive NK clones are detected in these individuals. The HLA-C group 2 receptor gene (KIR2DL1) is present in approximately 97% of donors. When the gene is present, high-frequency alloreactive NK clones are detected in donors. The KIR3DL1 HLA-Bw4 receptor gene is present in only around 90% of individuals. Even when the gene is present, alloreactive NK clones occur in highly variable frequencies and are detected in two-thirds of donors. Thus, functional assessment of the donor NK repertoire appears necessary.

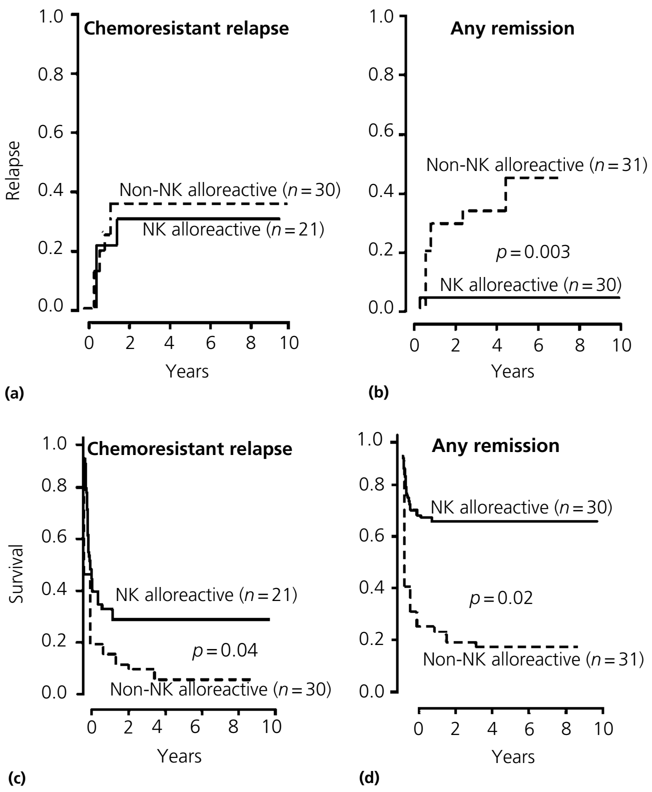

Figure 44.7 Transplantation from haploidentical natural killer (N-alloreactive donors controls relapse in acute myeloid leukemia and improves event-free survival. (a) Relapse in patients transplanted in chemoresistant relapse from NK-alloreactive versus non-NK-alloreactive donors. (b) Relapse in patients transplanted in any remission from NK-alloreactive versus non-NK-alloreactive donors. (c) Event-free survival in patients transplanted in relapse from NK-alloreactive versus non-NK-alloreactive donors. (d) Event-free survival in patients transplanted in complete remission from NK-alloreactive versus non-NK-alloreactive donors. Data source: Ruggeri et al. [155].

NK cell alloreactivity was associated with no difference in post-transplant relapse (32% vs. 37%; p = NS) (Figure 44.7), although it was associated with improved event-free survival (0.48%; 95% CI 0.29–0.78; $p < 0.001$) (Figure 44.7). Based on these data, donor NK cell alloreactivity against recipient cells has become a selection criterion for HLA-disparate donors when a T-cell-depleted protocol is employed.

The 67% probability of surviving event-free for AML patients transplanted in any remission from NK-alloreactive donors is in the range of best survival rates after transplantation from unrelated donors and cord blood units. The 34% event-free survival of patients transplanted in chemoresistant relapse from NK-alloreactive donors is also remarkable. Each of the three KIR ligand mismatches (C1, C2, Bw4) provided a survival advantage over non-NK-alloreactive transplants. NK cell alloreactivity provided better protection from leukemia relapse when exerted by maternal donor [22], presumably because of an additive effect provided by memory T cells against the child's paternal HLA haplotype as a result of maternal exposure to fetal antigens during pregnancy. Results from clinical trials showed NK cell alloreactivity was an effective form of immunotherapy in pediatric ALL as a lower incidence of ALL relapse was observed [156–158]. Several observations suggest alloreactive NK cells are responsible for favorable transplantation outcomes. Transfer of human alloreactive NK cells into NOD-SCID mice eradicated previously transplanted human AML cells [154]. KIR ligand mismatches correlated with the ability of donor NK cell clones to kill cryopreserved hematopoietic recipient cells, including leukemic cells [153–155]. Most importantly, engrafted HSCs give rise to an NK cell repertoire that includes donor-versus-recipient alloreactive NK clones that kill cryopreserved hematopoietic recipient cells, including leukemic cells [153]. Donor-versus-recipient alloreactive NK clones are detected in vivo in recipients for up to 1 year after transplant [155].

One immediate consequence of these clinical findings is exploitation of NK cell alloreactivity in haploidentical donor selection. The search for NK-alloreactive donors may require extension beyond the immediate family to aunts, uncles, cousins, etc. In the afore-mentioned clinical studies, NK-alloreactive donors were found for around 50% of patients, which approaches the maximum because one third of the population express class I alleles belonging to all three class I groups recognized by KIRs and block NK cells from every donor.

How is an NK-alloreactive donor selected? Recipients who express alleles belonging to one or two of the three class I allele groups recognized by KIRs may find NK alloreactive donors. Donors who are HLA-C group mismatched with their recipients possess high-frequency NK clones that are alloreactive against recipients' target cells [153–155]. Thus, high-resolution HLA-C typing is a good predictor of NK cell alloreactivity (Tables 44.4 and 45.5). Since 3% of individuals do not possess the KIR2DL1 gene [155,105,114], the combination of a KIR2DL1$^-$ donor and a recipient without HLA-C group 2 alleles could result in a 1.5% incidence of false positivity. KIR2DL1 gene typing of the donor may be necessary to assess the NK-alloreactive potential of this combination.

In HLA-Bw4 mismatches, even when the KIR3DL1 gene is present in the donor (~90% of individuals) [145,153,159], NK repertoire studies show that alloreactive NK clones are non-detectable in around one third of individuals [90]. In some, allelic variants in the HLA-Bw4 inhibitory NK receptor gene *KIR3DL1* may not allow full receptor expression at the cell membrane and affect NK cell inhibition by the HLA-Bw4 ligand [160,161]; others apparently express alloreactive NK clones in very low frequencies. Thus, for HLA-Bw4 mismatches, functional assessment of the donor NK repertoire appears necessary.

As approximately half of unrelated donor transplants are mismatched for one or more HLA class I alleles, donor versus recipient NK cell alloreactivity may also occur in this setting. However, some retrospective studies show no advantage in transplantation from KIR ligand-mismatched donors [162–166]. Unrelated donor transplant protocols are heterogeneous in conditioning regimens, patient populations, and underlying diseases. They most commonly use T-cell-replete bone marrow harvests or, nowadays more frequently, peripheral blood progenitors that contain approximately 4 log more T cells than haploidentical grafts. Relatively few transplanted HSCs, combined with the high T-cell graft content and post-transplant immune suppression, have been associated with poor reconstitution of potentially alloreactive, KIR-bearing NK cells [167,168]. Other studies have observed an increased graft-versus-leukemia effect of KIR ligand-mismatched transplants [169–174]. A marked survival advantage was reported in patients who received ATGs pre-transplant to produce in vivo T-cell depletion, and a graft containing two- to threefold more nucleated cells than usual in unrelated donor transplantation for a population containing a high proportion of children [169]. Prospective studies are needed to determine whether strategies such as high doses of HSCs, T-cell depletion, and no post-transplant immune suppression, which harness donor-versus-recipient NK cell alloreactivity in haploidentical transplantation, can be implemented to improve outcome in more closely HLA-matched unrelated donor transplants.

Since the original report that NK cell alloreactivity in haploidentical transplantation rests upon KIR ligand mismatching and donor NK-cell recognition of "missing self" on recipient targets [154], the "missing ligand" model has been proposed as a powerful algorithm for predicting favorable transplant outcomes not only in haploidentical transplants [156,157], but also in matched sibling [175] and in unrelated donor transplants [176]. Under the perturbed conditions that exist after an HCT, it is hypothesized that NK allogeneic reactions occur when KIR ligand-matched donors possess an "extra" KIR for which neither donor nor recipient has an HLA ligand. These donors may carry KIR-bearing NK cells in an anergic/regulated state that, upon transfer into the recipient, are hypothesized to become activated and exert a GVLE.

However, even though self-tolerant NK cells that do not express inhibitory receptors for self-MHC have been described in mice [177–180] and humans [181], no studies have as yet determined whether tolerant NK cells acquire/resume cytotoxic effector function after transplant. When an adult series of AML patients transplanted from HLA-incompatible donors was analyzed according to the "missing ligand" algorithm, the "missing ligand" transplant recipients disappointingly had a worse prognosis than patients transplanted from NK-alloreactive (KIR ligand-mismatched) donors [155]. While differences in diseases, age of patients, and transplantation protocols, such as ATG [155] versus no ATG in the conditioning regimen [173–181], or peripheral blood CD34$^+$ cells [155] versus bone marrow [180,181] as a source of hematopoietic cells, may account for these conflicting results, the analysis shows that donor NK cell recognition of "missing self" on recipient targets is essential for triggering powerful NK cell allogeneic reactions that are beneficial for transplant outcomes. Indeed, a recent study demonstrated that NK cells that did not express receptors for self-HLA remained hypofunctional throughout NK cell reconstitution after HLA-matched transplantation, thus precluding any clinical benefits through breaking of NK cell tolerance [182].

Conclusion

Transplant results have demonstrated that an increasing degree of donor HLA incompatibility is associated with a proportionally increased risk of graft failure, GVHD, and transplant-related mortality. Initial studies utilizing T-cell-replete marrow transplants found that donor incompatibility for two or three HLA antigens represented a formidable barrier to success, did not allow sufficient control of GVHD, and led to unacceptably low patient survival. Great effort has been invested to investigate innovative approaches to overcome the HLA barrier. Hematopoietic growth factor-mobilized PBPCs have increased the probability of engraftment. Pre-transplant ATG plus intensified postgrafting immunosuppression or high-dose CY administered after transplantation have been developed to more effectively prevent GVHD. These new approaches have gained popularity because clinical results are promising and because they do not need dedicated laboratory facilities or specialized staff for cell manipulation. Clinical research on T-cell-depleted HCT from HLA haploidentical donors for the treatment of acute leukemia has been proceeding for over 20 years in centers worldwide. The use of T-cell-depleted marrow grafts has decreased acute and chronic GVHD, but at the expense of increased graft failure and leukemia relapse, and impaired immune reconstitution, leading to no advantage in survival. The use of T-cell-depleted PBPC has led to high probability of engraftment and GVHD prevention, it has proved crucial for the development of NK cell alloreactivity, which is important for the control of AML, and continues to offer opportunities for innovative immunotherapeutic strategies.

CHAPTER 45

Hematopoietic Cell Transplantation from Unrelated Donors

Effie W. Petersdorf
Fred Hutchison Cancer Research Center and University of Washington, Seattle; Seattle Cancer Care Alliance, Seattle, WA, USA

Introduction

Unrelated donor hematopoietic cell transplantation (HCT) is the fastest growing modality of allogeneic transplantation worldwide, with more than one third of patients older than 50 years of age (www.cibmtr.org; [1–3]). The increased safety, efficacy and availability of the procedure are the result of the development of less toxic conditioning regimens and improved graft-versus-host disease (GVHD) prevention and treatment strategies, recognition of the importance of comprehensive and precise donor human leukocyte antigen (HLA) matching, the availability of molecular technologies for the early detection of recurrent malignancy, the development of immunotherapeutic strategies for the treatment of recurrent disease, and improved supportive care of patients. Collectively, these advances have led to improved survival rates comparable to those after HLA genotypically identical sibling transplantation particularly for good-risk patients [4–8].

There has been a greater appreciation of the many factors that influence the success of unrelated donor HCT. Some factors that impact transplant outcome can be modified and/or choices are available, and thus provide the patient and physician with a means to plan the transplant at a time when these factors are optimal. Perhaps the best example of a modifiable factor is the HLA-match status of the donor. When a suitably matched donor is not available, a search can be continued until a better matched donor is identified, provided the patient's clinical status remains stable and the disease is well controlled. Other factors such as patient age cannot be changed, and yet other variables, such as comorbid medical conditions, may be difficult to modify. It has long been recognized that the success of allogeneic transplantation from related or unrelated donors is strongly influenced by the underlying malignancy and the burden of disease at the time of transplantation. For the individual patient, when to time the transplant, how the transplant should be performed, and from which donor, can be a complex decision that requires careful assessment of the risks and benefits.

Central to the success of an unrelated donor transplant is the ability to surmount the "transplantation barrier." The concept that GVHD is a complex disease of polygeneic etiology shaped by "environmental" factors, such as the conditioning and immunosuppressive regimens, provides a framework for understanding the immunogenetics of the transplantation barrier. The known genetic determinants involved in GVHD and the graft-versus-tumor (GVT) effect are genes of the HLA and the natural killer (NK) families, cytokine, and immune response genes. Identification of single genes of importance in transplant outcome is but the first step in understanding the basis of the transplantation barrier. The role of gene–gene interactions is increasingly recognized, and the inflammatory environment in which these interactions occur provides a basis for understanding individual patient susceptibility to GVHD and the strength of GVT. In turn, the impact of genetic effects varies with different conditioning regimens (high dose and reduced intensity) and immunosuppressive therapy (including manipulation of the graft, T-replete versus T-deplete grafts, and different methods for depletion), and with different cell sources [bone marrow (BM), peripheral blood progenitor cells (PBPCs) or cord blood]. Indeed, elucidation of the many genetic and environmental factors that influence outcome will continue to require methodical analysis of very large well-characterized transplant populations with complete clinical data.

The recent availability of a sequence of the human genome (www.hapmap.org) provides the much-needed map to identify the genes that constitute the transplantation barrier. With the technical ability to detect single-nucleotide polymorphisms (SNPs) in gene sequences between recipients and donors, however, our understanding of the extent and nature of human diversity is far ahead of what is known about the functional consequences of that genetic variation. Ultimately, how best to integrate genetic information into day-to-day clinical practice to benefit the individual patient will require continued clinical research on both the genetics front as well as in the development of novel prevention and treatment strategies. In this chapter, the major advances that have contributed to the increased safety, efficacy, and availability of unrelated donor transplantation are described. The reader is directed to Chapters 10, 29 and 37 for topics related to unrelated donor HCT and to Sections 5 and 6 for in-depth discussion of specific disease indications.

Patient factors

One of the most challenging aspects of planning transplantation for patients who lack a related donor is determining *who* can benefit from an unrelated HCT, *when* the transplant should be performed, *how* the transplant should be carried out, and *which* donor should be chosen. The development of reduced-intensity and non-myeloablative conditioning regimens now no longer restricts the use of unrelated donor HCT to only younger patients. In general, good candidates for unrelated donor HCT include patients who otherwise would be

considered for a matched sibling donor transplant had a matched sibling been available [9]. Individualized risk assessment is a critical step early in the process of planning an unrelated donor transplant and is facilitated by robust, validated risk factor indexes [10,11]. One such instrument is the European Group for Blood and Marrow Transplantation (EBMT) Risk Score which was originally developed to aid decision making for the timing of transplantation for CML [10]. Its parameters include patient age, disease stage, time from diagnosis to transplant, whether the stem cell donor is an HLA-matched sibling or other allogeneic stem cell donor, and patient–donor gender. An important feature of the risk score is the concept that the effects conferred by each of the five individual features are informative for additive negative effects.

Patients derive the greatest benefit from unrelated HCT when transplantation is performed with the lowest leukemic burden, using HLA-matched donors, and timed when the patient can best tolerate the transplant procedure. The dramatic impact of disease stage is best seen among recipients of HLA-A, -B, -C, -DRB1, and -DQB1 allele-matched unrelated donor HCT. The strong influence of disease diagnosis and stage at time of transplantation among allele-matched transplant recipients was validated in a National Marrow Donor Program (NMDP) and Center for International Blood and Marrow Transplant Research (CIBMTR) study wherein 5-year survival for good-, intermediate-, and high-risk leukemia was 63%, 48%, and 31%, respectively [12]. Patient survival was not affected by donor age, donor parity, donor cytomegalovirus status, or donor gender. Similar results were found in a single-center study, where survival at 10 years after transplantation for good-, intermediate-, and high-risk disease was 78%, 45%, and 35%, respectively [13] (Figure 45.1).

The three major indications for unrelated donor HCT are AML, ALL, and MDS (www.cibmtr.org; [1]). The reader is referred to Sections 5 and 6 of this volume for in-depth discussion of specific disease indications.

Acute myeloid leukemia

Transplantation from HLA-matched unrelated donors is associated with similar survival to that from HLA genotypically matched siblings for patients with AML [6,14,15]. If a patient is a good candidate for an allogeneic transplant but lacks a sibling donor, then an unrelated donor should be considered. As discussed in Chapter 50, historically cytogenetic markers have served as a foundation for classification schemes to define patients at low, intermediate, and high risk of disease recurrence after conventional and transplant therapy [16–18]. Low-risk de novo AML patients include those with the t(8;21) and inv(16) karyotypes, and the t(15;17)(q22;q12–21)$^+$ acute promyelocytic leukemia subtype. These patients enjoy a high response rate to conventional chemotherapy and a low (35%) probability of disease recurrence after first complete remission (CR1) is attained. For low-risk patients who lack an HLA-identical sibling donor, unrelated HCT in CR1 is associated with a high transplant-related mortality (TRM) that outweighs the benefits of the GVT effect compared with chemotherapy [19]. When a patient with good-risk features relapses, however, HCT in second complete remission (CR2) is indicated. Unrelated donor HCT should also be considered when a patient is unable to complete induction/consolidation therapy as planned.

High-risk AML karyotypes include -5, -7, inv(3) or complex karyotypes, defined as containing at least three chromosomal aberrations. The probability of disease recurrence among high-risk patients is 80% after CR1, and the probability of achieving CR2 is very low. For these patients, allogeneic HCT in CR1 remains the best option to prevent relapse [20,21]. Survival, disease-free survival (DFS), and relapse after unrelated HCT for high-risk AML in remission may be comparable to those obtained after related donor HCT, especially when the transplant can be performed in remission (www.cibmtr.org) [16]. A second group of very high-risk patients includes those who fail primary induction chemotherapy. Application of unrelated HCT for salvage in these patients requires individualized risk assessment. Patients requiring fewer than three courses of induction chemotherapy prior to transplantation, a low percent of marrow blasts and CMV seropositivity were favorable risk factors [22]. These results support the immediate initiation of an unrelated donor search for patients who fail to achieve a complete remission after the first attempt.

Historically, patients with normal cytogenetics were classified as "intermediate" risk, with a 50% probability of disease recurrence after CR1, and low chances that CR2 can be attained. In a retrospective CIBMTR analysis of unrelated HCT for AML in CR1 and CR2, the 5-year DFS for CR1 patients with favorable-, intermediate-, and poor-risk cytogenetics was 29%, 27%, and 30%, respectively; OS at 5 years for the same three groups was 30%, 29%, and 30%, respectively [23]. When unrelated HCT was performed in CR2, 5-year DFS for patients with favorable-, intermediate-, and high-risk cytogenetics was 42%, 38%, and 37%, respectively; OS at 5 years was 35%, 45%, and 36%, respectively. Patients with high-risk cytogenetics had a high risk of relapse after HCT, but the overall outcome after transplantation was superior to that with chemotherapy. Relapse after HCT was higher for patients with unfavorable cytogenetics whether

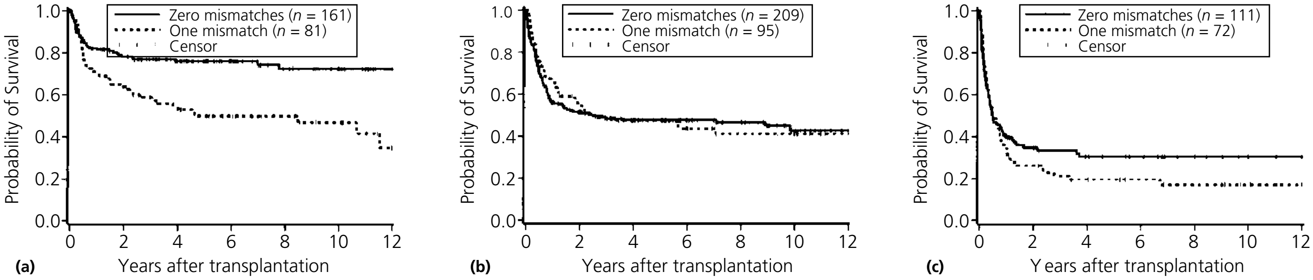

Figure 45.1 Impact of disease stage and human leukocyte antigen allele matching at the time of unrelated donor transplantation. (a) Low-risk chronic myeloid leukemia [chronic phase (CML-CP) and transplantation within 2 years of diagnosis]. (b) Intermediate-risk hematologic malignancies [CML-CP and transplantation more than 2 years from diagnosis; CML acute phase and CML blast phase/remission (CML-BP/rem), and transplantation within 3 years of diagnosis; acute leukemia in remission; myelodysplastic syndrome-refractory anemia]. (c) High-risk hematologic malignancies (CML-BP; CML acute phase and CML-BP/rem, and transplantation more than 3 years from diagnosis; acute leukemia in relapse; myelodysplastic syndrome beyond refractory anemia). Source: Petersdorf et al. 2004 [13]. Reproduced with permission of the American Society of Hematology.

the transplant was performed in CR1 or CR2, and there was evidence that there was less of a GVT effect with transplantation for high-risk AML in CR1 or CR2. More recently, molecular mutation data suggest that there are subgroups of better-risk and poorer-risk patients within the intermediate-risk group, based on nucleophosmin (NPMI), fms-related tyrosine kinase-3 (Flt3), and CCAAT/enhancer-binding protein α (CEBPA) markers [24]. NPMI mutations are generally associated with improved survival, in contrast to Flt3 mutations which have high potential for disease recurrence [25]. CEBPA is generally associated with a favorable prognosis [26]. In related donor transplantation, patients with the Flt3 mutation benefited significantly from transplantation, whereas patients without Flt3, regardless of their NPMI or CEBPA marker status, derived no benefit [26]. Hence, newer classification schemes incorporate molecular markers to refine risk strata within the intermediate-risk group of patients which have prognostic significance (Chapter 50) [27].

The clinical challenges for treating older patients with AML rest on the toxicities associated with both conventional chemotherapy as well as with the transplant conditioning regimen. A prospective single-center study designed to evaluate the applicability of reduced-intensity conditioning for related or unrelated donor transplantation found a 57% DFS among patients who underwent transplantation, an outcome that was superior to that of patients who did not have a transplant due to no donor [28]. These results support the application of reduced-intensity conditioning for older patients who, despite their chronological years, are excellent candidates for allogeneic transplantation.

Acute lymphoid leukemia

Unrelated donor HTC for acute lymphoid leukemia (ALL) is potentially curative [29]. Survival after unrelated HCT for ALL in CR1 is 42% compared to 48% after sibling donor HCT [30,31] (www.cibmtr.org). The prognostic indicators for high-risk adult ALL can be used to plan allogeneic transplantation. Factors associated with a high risk of disease recurrence include older patient age at diagnosis (>35 years), total white blood cell count >30,000/μL at diagnosis, failure to attain a first CR with conventional chemotherapy, and presence of the t(4;11) pro-B cell karyotype, t(9;22) translocation, hypodiploidy, and the rare t(1;19) karyotype.

The findings of a recent evidence-based review support unrelated donor transplantation for high-risk ALL in CR1, but not for standard-risk ALL [32]. For patients in CR2, transplantation from related or unrelated donors yields comparable survival, both superior to chemotherapy alone and to autologous HCT. Some very high-risk patients who relapse after chemotherapy may be salvaged with unrelated donor HCT [33]. The design of effective and less toxic conditioning regimens hold promise for controlling disease long term especially for older patients with comorbidities [34,35].

Myelodysplastic syndrome

Allogeneic transplantation is the only known cure for MDS [36]. The major limitation of allogeneic transplantation is disease recurrence among patients with advanced MDS and/or high-risk karyotype [37,38]. Since this disease is generally a disorder of older patients, high TRM has been observed with traditional conditioning regimens, and has led to the application of non-ablative conditioning approaches. A careful assessment of individual risk factors that may increase TRM is critical. The disease morphology, blast count, neutrophil count, disease duration, patient age, and cytomegalovirus serostatus all influence transplant outcome for MDS. The International Prognostic Scoring System stage at the time of transplantation strongly correlates with the risk of post-transplant disease recurrence, and can aid in the identification of patients who might benefit from HCT early after diagnosis.

Unrelated donor HCT for early MDS shows a low probability of disease recurrence. Data from the CIBMTR find that overall survival rates for adults are within 10–20% of those after HLA genotypically matched sibling transplantation [39]. When the disease has advanced with excess blasts, and when cytogenetics indicates higher risk disease (-5 or -7, or complex cytogenetic abnormalities), initiation of the unrelated donor search and careful monitoring of marrow function are critical. When MDS has advanced to AML, high relapse rates are seen after transplantation. The integration of hypomethylating agents both pre- and post-transplant into the treatment strategy remain important goals for the future [40,41].

Transplant factors

The effects of HLA mismatching after reduced-intensity conditioning, particularly at HLA-C, are similar to those observed after ablative conditioning, namely increased risk of clinically severe acute GVHD, increased non-relapse mortality, and lower overall survival [42,43]. Hence, the principles of HLA matching, which include limiting the total number of HLA mismatches and avoidance of HLA-C mismatching, hold true for both ablative and non-myeloablative approaches. A larger non-myeloablative transplant experience will be necessary to fully evaluate the relative risks associated with specific HLA locus mismatches and with allele versus antigen mismatches. The negative effects of HLA mismatching after non-myeloablative conditioning may be abrogated with the use of promising novel GVHD regimens [18].

Product factors

Over 60% of all allogeneic transplants performed worldwide today use PBPCs [2,3]. The source of hematopoietic cells influences transplant outcome. The BMT Clinical Trials Network completed a phase III multicenter randomized study of unrelated donor BM versus PBSC transplantation [44]. The overall 2-year survival rates in the PBSC and BM groups were 51% and 46%, respectively ($p = 0.29$); however, major differences in graft failure (3% vs. 9%; $p = 0.002$) and chronic GVHD (53% vs. 41%; $p = 0.010$) were observed. Therefore, PBSC transplantation was associated with higher rates of engraftment and chronic GVHD, whereas BM was associated with lower rates of engraftment and chronic GVHD. These findings open new strategies for the individualized use of PBSCs in clinical settings where engraftment is a major concern.

Donor factors

One of the most important aspects of planning an unrelated donor transplant is to avoid, whenever possible, the “urgent” donor search situation. As detailed in Chapter 10, the availability of high-throughput HLA typing laboratory support has decreased the time required to identify well-matched donors. Depending on the patient’s genotype, it is currently feasible to offer transplantation for high-risk patients within 3 months. For patients with high-risk features at diagnosis, prompt initiation of an unrelated donor search provides sufficient time for a suitable donor to be identified and for the transplant procedure to be performed when the disease is in remission. For all patients, but particularly high-risk patients, the identification of back-up donors provides options and avoids delays when the primary donor is unable to donate, or when the patient's condition changes [45].

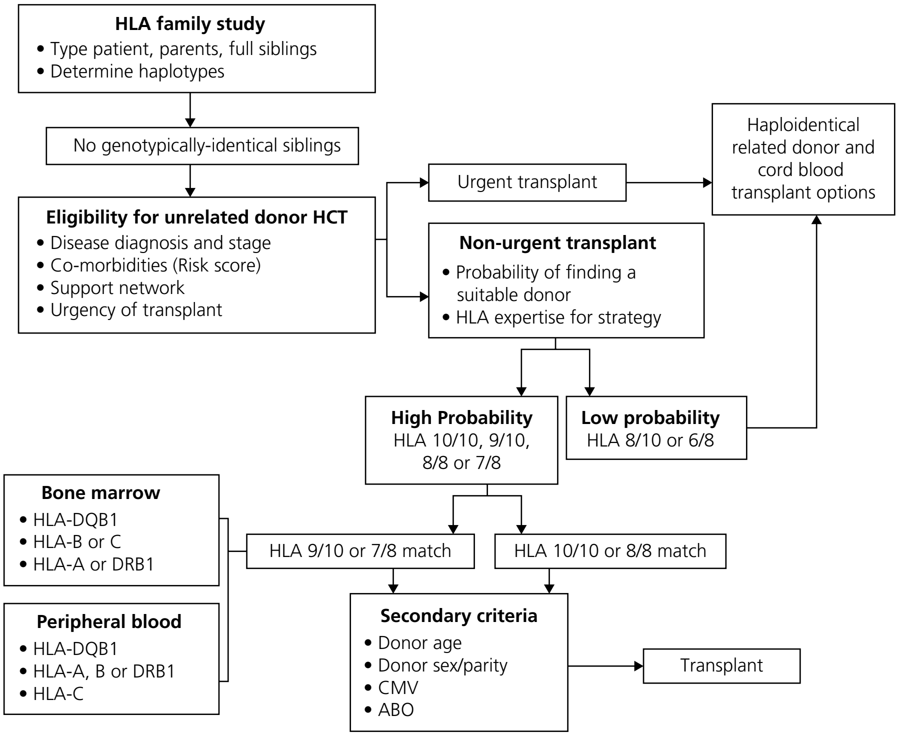
The roles of donor age [5,46], donor sex [47], and CMV serostatus [46], have been extensively investigated as predictive factors in unrelated donor HCT, although recent registry data suggest only donor HLA [12] is a factor for survival. After HLA criteria are used to select among potential unrelated donors, further selection based on CMV negativity for CMV-negative recipients and avoidance of multiparous female donors for male recipients are often used by transplant centers when several otherwise equivalent donors are available (Figure 45.2).

Increased awareness of donor health and safety has prompted international efforts to standardize donor recruitment, management, and informed consent through two registries, the Serious Events and Adverse Effects Registry (SEAR) and the Serious Product Events and Adverse Effects Registry (SPEAR) [48]. These safety nets are designed for the reporting of donor events leading to life-threatening disease, death, in-patient hospitalization, or disability (SEAR). The stem cell product, the quality of the graft, labeling of the product, infusion reactions, unpredictable risk of transmissible infection, serious transportation problems, or damage to the cells during transport, are surveyed by SPEAR.

The unrelated donor search process

HLA studies are performed on the patient, parents, and full siblings to determine the availability of an HLA genotypically identical sibling donor (Figure 45.2). The resolution of HLA typing usually entails intermediate-high resolution of HLA-A, -C, -B, -DRB1, and -DQB1. When maternal and paternal haplotypes share antigens, high-resolution typing is required to define heterozygosity for two different alleles. A preliminary unrelated donor search is undertaken through Bone Marrow Donors Worldwide (BMDW; www.bmdw.org), a comprehensive datafile of unrelated donors and cord blood units currently on file in registries and banks worldwide. As of May, 2015, there are over 25 million registered unrelated donors. The likelihood of identifying HLA 8/8 or 10/10 matched donors ranges from 20% to 80% and depends on the recipient's genotypes and haplotypes, and the size and composition of the donor registries (www.worldmarrow.org; www.nmdp.org). A preliminary search of the BMDW provides clinicians with an excellent overview of the likelihood that suitably matched unrelated donors can be identified. The BMDW preliminary search does not offer direct access to donors or cord blood units for actual work-up, but provides essential information that can guide the search team and clinicians on the potential difficulties in identifying suitable donors, and hence an anticipated timeline for coordinating the transplant.

For potentially matched donors that lack sufficient HLA typing on all loci of interest or incomplete high-resolution typing, a strategy



HLA family study
• Type patient, parents, full siblings
• Determine haplotypes
No genotypically-identical siblings
Eligibility for unrelated donor HCT
• Disease diagnosis and stage
• Co-morbidities (Risk score)
• Support network
• Urgency of transplant
Urgent transplant
Haploidentical related donor and cord blood transplant options
Non-urgent transplant

Transplant

Figure 45.2 The unrelated donor search process and selection of donors. The search process begins with complete family typing where the patient's tissue type is confirmed through segregation of the maternal and paternal HLA haplotypes. Eligibility for unrelated donor HCT is an important early step where the urgency of the transplant is determined. For very urgent clinical situations, consideration of a haploidentical related donor or cord blood transplant is appropriate. For non-urgent cases, input from HLA experts may greatly facilitate the search and selection process. Patients whose searches yield only highly mismatched donors may be candidates for haploidentical related donor or cord blood transplantation. Searches that yield one or more suitable donors proceed to typing of donor samples for confirmatory typing. When several donors with a single mismatch (9/10 or 7/8) are under consideration, the preferred mismatched HLA locus may depend on the source of stem cells. For bone marrow, high risks are observed with HLA-A and -DRB1 mismatches, and low risk for -DQB1; for PBPC, high risks are observed with HLA-C mismatches, and low risk for -DQB1 [12,58]. Secondary criteria may be applied to select the donor for the transplant, and potential back-up donors.

for typing donor samples to maximize the yield of identifying at least one acceptable donor and back-up donors is important. When the BMDW report shows only potential HLA-mismatched donors, guidance from HLA experts at this early stage of the search is highly desirable. Several strategies based on known allele, antigen, and haplotype frequencies in world populations can be used to direct the donor search towards mismatching for one specific HLA determinant in an attempt to match at all remaining loci, thus limiting the total number of HLA mismatches. Allele and haplotype frequencies are available from several sites including http://allelefrequencies.net; http://hla.alleles.org; http://www.ebi.ac.uk/ipd/imgt/hla/; http://bioinformatics.nmdp.org; http://hlexplorer.net; and http://pypop.org (websites accessed February 2, 2015).

Once a formal search is initiated, transplant centers begin the typing process to confirm the HLA match status of donors of interest. Since donors may not have complete typing on HLA-A, -C, -B, -DRB1, the NMDP has developed a program, HapLogic™, to estimate the likelihood that donors are potentially HLA matched with the patient (http://www.ebi.ac.uk/ipd/imgt/hla/searchdet_nmdp.html; accessed February 2, 2105). The concept is that even though an HLA locus has not been typed, information at the other typed loci can permit probability estimates that the sample encodes a specific HLA determinant. Allele codes used by the National Marrow Donor Program (NMDP) provide information on the possible four-digit allele that could be encoded in a donor sample. This information is helpful for prioritizing the HLA typing of donors to maximize the chances that a high-resolution matched donor can be identified [49]; http://bioinformatics.nmdp.org (accessed February 2, 2015).

Donors are volunteers. Different circumstances may arise long after the donor has registered that preclude donation such as medial deferral or loss of contact; donor issues have also included unavailability for the desired dates and wrong tissue typing. The importance of back-up donors is critical to the coordination of an unrelated donor transplant [45,50]. When the clinical status of the patient is ultra-urgent, then consideration of haploidentical related donors and cord blood units is appropriate.

Donor selection

GVHD is commonly observed after unrelated HCT, and is a complex phenotype shaped by both genetic and "environmental" factors. As a complex phenotype, GVHD has a polygenic etiology. The genes known to be involved in the pathogenesis of GVHD are the HLA, killer immunoglobulin-like receptor (KIR), and cytokine genes. Although the recipient's genotypes are not modifiable, the potential to select a donor with the "optimal" genetic make-up to reduce GVHD and TRM is feasible. The environmental factors that influence a given patient's risk of GVHD are contributed by the chemotherapy- and radiation-containing regimens used to prepare the patient, the immunosuppressive agents used to prevent and treat GVHD, and the source of donor stem cells, to name but three important factors. To a great extent, these conditions can be modified to fit each patient's need, and there has been tremendous progress in the development of novel approaches such as reduced-intensity conditioning regimens.

Recognition that a complex phenotype such as GVHD arises from the effects of more than one gene is an important platform for future research in immunogenetics. Gene–gene interactions may vary under widely different transplant procedures and with different approaches for GVHD prevention and treatment, and might explain the heterogeneity of results reported from different studies. As more information becomes available on the extent of HLA, NK, and immune response gene diversity in human populations, it is appreciated that the race of the recipient and donor plays a major role in defining the genetics of a given transplant. A full understanding of the genetic basis of host-versus-graft (HVG) and graft-versus-host (GVH) alloreactivity will come from the continued evaluation of racially and ethnically diverse populations.

This section reviews the sentinel advances in the identification of the immunogenetic risk factors in unrelated donor HCT: major histocompatibility (MHC) region genes and haplotypes, HLA–NK interactions, and cytokine and immune response genetics. Based on extensive worldwide experience, the current criteria for the selection of unrelated donors are (Figure 45.2; Table 45.1):

1. Type for 10 alleles (high resolution) at HLA-A, -B, -C, -DRB1, and -DQB1.
2. Match for a minimum of 8/8 high-resolution defined HLA-A, -B, -C, and -DRB1 determinants [12,13,51–55].
3. When several 10/10 donors are available, some centers type and match for HLA-DPB1 ("12/12" donors) and consider permissible HLA-DPB1 mismatches [56,57].
4. When there are no 10/10 matched donors, use of a donor with an isolated HLA-DQB1 mismatch may be acceptable [12].
5. When donors with mismatching at HLA-A, -B, -C, or -DRB1 must be considered, the selection of mismatched donors may depend on the graft source. *Marrow* grafts from HLA-A and -DRB1-mismatched donors are the most risky, followed by HLA-B and -C [12]. *PBPC* grafts from HLA-C antigen mismatched donors are the most risky, followed by HLA-A and -B.
6. When a mismatched donor is considered, allele mismatches are as risky as antigen mismatches at HLA-A, -B, -DRB1. At the HLA-C locus, antigen mismatches are more risky than allele mismatches [12,58].

The data that support these criteria are derived from retrospective research studies that employed high-resolution typing at all loci, had sufficient power to detect statistically significant differences when they exist, and used multivariate analysis to control for non-HLA variables that affect clinical outcome [59,60] (Table 45.1) and are summarized as follows:

Which HLA loci should be typed? A "matched" donor may be defined on the basis of high-resolution allele definition at four loci – HLA-A, -B, -C, -DRB1 ("8/8") – or five loci HLA-A, -B, -C, -DRB1, -DQB1 ("10/10") – or 6 loci HLA-A, -B, -C, -DRB1, -DQB1, -DPB1 ("12/12"). HLA 10/10 matched transplants have superior DFS compared with any mismatch [12,13,52,53]. The impact of donor HLA matching is especially dramatic for a subset of good-risk patients with AML, MDS, ALL, and CML; transplantation using a high-resolution matched unrelated donor can yield survival rates that are very similar to those seen after HLA-identical sibling transplantation (www.marrow.org) [12,13,61–66] (Figure 45.1).

More recently, a minimal level of matching has been defined among HLA-A, -B, -C, -DRB1 genes [12]. In this analysis of 3860 patients transplanted from unrelated donors following myeloablative conditioning, high-resolution matching at HLA-A, -B, -C, and -DRB1 was associated with highest survival rates. Outcomes following a 10/10 matched HCT were comparable to those after 9/10 HCT when the single mismatch was at HLA-DQB1, indicating that the 8/8 high-resolution matched unrelated donor can be used as a predictor for patient survival. Based on these findings, the NMDP recently recommended the use of 8/8 matching criteria for all retrospective research studies employing HLA data [59]. For prospective donor search and selection, information on HLA-DQB1 becomes

Table 45.1 Role of HLA in unrelated donor hematopoietic cell transplantation

Model	Locus	Graft failure	Graft-versus-host disease	Graft-versus-leukemia effect	Survival	Comments
Single locus mismatch	A	[51,52]	[12,52–54]		[12,52–54]	Antigen mismatches are associated with higher risks than allele mismatches [53]. TRM is increased with any mismatch [12]. HLA-A mismatch is high risk in BM HCT [12] and intermediate risk in PBSC HCT [58].
	B	[51,52]	[12,54]		[13,53,54]	Antigen mismatches are associated with higher risk than allele mismatches [53]. TRM is increased with any mismatch [12]. HLA-B mismatch is intermediate risk in both BM and PBSC HCT [12,58].
	C	[51,55]	[52,54]	[52]	[13,53]	Single allele or antigen mismatches are detrimental, notably HLA-C in low-risk patients [13]. Antigen mismatches are associated with higher risk than allele mismatches [12,53]. TRM is increased with any mismatch [12]. HLA-C mismatch is intermediate risk in BM, and high risk in PBSC [12,58].
	DRB1		[13,51,54]		[12,13,53]	Antigen mismatches are associated with higher risk than allele mismatches [53]. There is a trend for lower survival [12]. HLA-DRB1 mismatch is high risk in BM HCT [12].
	DQB1		[13]		[13]	HLA-DQB1 mismatch is low risk in BM and PBPC HCT [12,58].
	DPB1		[72]	[57,67]		HLA-DP is a classical transplantation antigen.
Epitopes	HLA-A, -B, -C, -DRB1		[77,80]	[81]	[77,80,81]	Residue 116 substitutions in class I are detrimental [77]. 15 high-risk allele mismatches are identified; 6 class I residues are identified as non-permissive [80]. Residues for acute GVHD may be different to those for relapse.
	HLA-DP		[56,71]		[71]	HLA-DPB1 HVG vector mismatches increase graft failure in thalassemia [71]. TCE permissive model provides approach for selecting lower risk donors who are DPB1-mismatched [56].
Haplotype	HLA-A, -B, -DRB1		[98]	[98]		Among HLA 10/10 matched transplants, haplotype matching was associated with higher severe acute GVHD, lower relapse, and no difference in overall survival compared to haplotype-mismatched transplants.
	Extended MHC		[69]			The presence of specific haplotypes in Japanese patients was associated with higher or lower GVHD risk.
	Common haplotypes		[99]			Presence of 1 or 2 common Caucasian haplotypes correlated with lower risk of grades II–IV acute GVHD.

Summary of studies that meet the criteria for an interpretable study: large populations typed at high resolution for a minimum of five loci (HLA-A, -B, -C, -DRB1, and -DQB1) and use of multivariable biostatistical methodology.
HVG, host-versus-graft; TRM, transplant-related mortality.

important when available donors have a known HLA-A, -B, -C or -DRB1 mismatch, because multilocus mismatching increases morbidity and mortality [12].

At which HLA locus is it acceptable to use a mismatched donor? Data on the relative risks of HLA mismatching have been largely drawn from patients receiving conventional GVHD prophylaxis (e.g., an antimetabolite and a calcineurin inhibitor). When a 10/10 matched donor cannot be identified, current data support the selection of donors with an isolated HLA-DQB1 mismatch (i.e., an 8/8 match at HLA-A, -B, -C, and -DRB1). However, when donors are mismatched HLA-A, -B, -C, or -DRB1, an HLA-DQB1 mismatch may increase morbidity and mortality [12,13]. CIBMTR data show that survival after 8/8, 7/8, and 6/8 transplantation was 52%, 43%, and 33%, respectively, a 9–10% survival decrement with each additional HLA mismatch [12]. When donors with mismatching at HLA-A, -B, -C, or -DRB1 must be considered, the selection of mismatched donors may depend on the graft source. Marrow grafts from HLA-A and -DRB1-mismatched donors are the most risky, followed by HLA-B and -C [12]. PBPC grafts from HLA-C antigen mismatched donors are the most risky, followed by HLA-A and -B [58]. Whether these same principles of HLA mismatching apply in the setting of T-cell depletion or use of Cytoxan after HCT as GVHD prophylaxis, remain to be determined.

The negative effects of HLA disparity on risk of graft failure [51,54,55], GVHD [12,51–54], and mortality are offset by the beneficial effects on GVL [52,54,67]. One clinical setting where multiple mismatches may be tolerable has recently been identified in Japanese patients transplanted for severe aplastic anemia, where any single or multiple HLA-C/DRB1/DQB1 mismatch did not lower survival or increase acute GVHD [68] and may be due to the more conserved HLA haplotypes in this population [69,70].

When there is a choice of donors, is there a difference between allele mismatches and antigen mismatches? When allele-matched donors are not available, selection among donors with allele or antigen mismatches is not always straightforward. Early data suggested that antigen mismatches conferred greater risks than single-allele mismatches (also previously referred to as "micro" mismatches) [53,55], implicating the immunogenicity of the number and nature of nucleotide substitutions in the peptide binding groove and TCR contact residues. Registry data indicate that allele mismatches are as risky as antigen mismatches at all HLA loci with the exception of HLA-C where antigen mismatches are more risky than allele mismatches [12,58]. These data are consistent with the graft failure study [55] where there was a predominance of HLA-C mismatches, and allele disparities did not contribute to the increased risk.

When should HLA-DPB1 be considered? HLA-DP is a classical transplantation antigen [57,67,71,72]. Six-locus 12/12 matching is associated with optimal outcome particularly for patients with low-risk disease [57]. Higher rates of GVHD are accompanied by lower rates of relapse, and suggest that HLA-DP can participate in the

GVT effect [56,66]. The negative effects of HLA-DPB1 mismatching are additive to haplotype-linked polymorphisms in the class III region of the MHC within the tumor necrosis factor (TNF) locus [73].

Because most HLA-A, -B, -C, -DRB1, -DQB1-matched donors are DPB1-mismatched, it has not been practically possible to identify DPB1-matched donors without significant typing resources and only in non-urgent clinical settings. Recently, a novel concept has been applied to identify permissible DPB1 mismatches [56] in which the specific immunogenetic amino acid residues of the polymorphic exon 2 were identified through cytotoxic T-cell assays, referred to as T-cell epitope (TCE) [71]. In an analysis of 8539 unrelated donor transplants, patients receiving a 12/12 matched donor had significantly higher risk of relapse and lower risk of grades III–IV acute GVHD compared to patients transplanted from a donor with a TCE-permissive DP mismatch. HLA 10/10 with a non-permissive DP mismatch, however, had significantly increased mortality, non-relapse mortality and grades III–IV acute GVHD. An HLA-A, -B, -C, -DRB1, or -DQB1 mismatch together with an HLA-DP TCE non-permissive mismatch was associated with the poorest survival compared to 12/12, 10/10 TCE-permissive or non-permissive, and 9/10 TCE-permissive donors. Patients transplanted from 9/10 TCE-permissive donors did not have significantly different risks of mortality compared to patient transplanted from 10/10 TCE-non-permissive donors. The beneficial effect has been confirmed [74]. For transplant centers wishing to use DPB1 TCE to select among HLA 10/10 matched donors, an interactive web-based tool has recently been developed for automated scoring of permissive or non-permissive DPB1 mismatch combinations (http://www.ebi.ac.uk/imgt/hla/dpb.html; accessed February 2, 2015).

Are there ancillary tools for predicting permissible HLA mismatches? "Permissible" HLA mismatches may be defined by polymorphisms that alter the peptide repertoire or that directly contact the T-cell receptor (TCR). Several approaches have been used to identify the sequence variation that governs permissivity, including functional assay of cytotoxic T-lymphocyte precursor (CTLp) cells [75] and direct examination of sequence motifs [76]. Early studies identified substitutions at residue 116 of class I molecules as immunogenic epitopes [77]. More recently, models for exploring permissible HLA mismatches in North American [78] and Japanese [79,80] patients have been described. In a large retrospective study of 4866 unrelated donor transplants facilitated by the JMDP [80], Tyr9–Phe9 amino acid mismatch of HLA-A and the Tyr9–Ser9, Asn77–Ser77, Lys80–Asn80, Tyr99–Phe99, Leu116–Ser116, and Arg156–Leu156 mismatches of HLA-C were each associated with a significantly increased risk of severe acute GVHD. In a follow-up analysis of relapse, four HLA-C and six HLA-DPB1 mismatch combinations were identified with lower risk for relapse [81]. Bioinformatic strategies have thus far not been successful in predicting permissible mismatches for clinical practice [82–84].

When should a cord blood transplant or a haploidentical related donor transplant be considered? In the absence of prospective studies, side-by-side evaluation of retrospective studies of HLA-matched and -mismatched unrelated donor, cord blood, and haploidentical related donor HCT permits an algorithm for the selection of stem cell source (Figure 45.2). HLA-matched unrelated donor HCT has, on the whole, lower toxicity and better if not equivalent outcomes to cord blood transplantation (CBT) after ablative conditioning with respect to survival, acute GVHD and TRM [85–88]. Single CBT is associated with higher TRM but similar DFS and survival as HLA-matched unrelated donor HCT [87]; HLA-mismatched unrelated donor HCT has lower TRM but increased relapse when compared to double CBT [88]. Hence, when an unrelated donor search fails to identify an HLA 9/10 or 7/8 unrelated donor (i.e., only 8/10 or 6/8 donors are available), then consideration of cord blood or haploidentical related donor is indicated. Cord blood and haploidentical related donors are also indicated when there is clinical urgency (Figure 45.2).

New frontiers: the clinical importance non-HLA gene polymorphisms

Ethnicity and race

Ethnicity and race affect the probability of identifying 8/8 matched donors [89] and the success of transplantation [90–92] that cannot be ascribed to socioeconomic differences [91]. Low socioeconomic status regardless of race was also identified to have a negative impact on outcomes for all patients. One unifying hypothesis is the role of undetected genetic variation that could have different alleles or variants in one population but not others, described in the following section on HLA haplotypes [69,70,93].

HLA haplotypes

The trends for lower relapse after unrelated compared with matched sibling HCT suggest a more intense GVT effect that arises from undetected genetic disparity among unrelated individuals. Because of its gene density, the MHC is an attractive candidate region for novel genetic variation that may affect transplant outcome even in the HLA-matched setting. Several recent lines of evidence support the role of untyped MHC-resident genes in transplant outcome. An increased risk for bacterial infections and corresponding TRM at day 180 after transplant was found in recipients transplanted from HLA-E*01:01,01:01 homozygous unrelated donors [94]. Mapping studies conducted in Japanese and Caucasian transplant populations uncovered microsatellite-linked risks [95,96] pointing to the existence of non-HLA MHC-linked variation that is clinically relevant.

One successful approach for mapping the MHC has used information from HLA haplotypes to define regions that merit fine mapping. The concepts are based on the strong positive linkage disequilibrium (LD) between HLA alleles and non-HLA variants. Because HLA allele-matched unrelated donors and recipients are not related to one another, the physical linkage of donor HLA alleles to one another may be different from that of the recipient's haplotypes (Figure 45.3). Hence, 10/10 matched unrelated donors and recipients who have the same haplotype linkage of HLA alleles may be more similar to each other with respect to undetected MHC variation than are 10/10 allele-matched pairs whose HLA haplotypes differ. A long-range phasing method was developed to specifically test these hypotheses [97], and when applied to 10/10 allele-matched unrelated donor–recipient pairs, uncovered a 20% frequency of haplotype mismatching [98]. Haplotype mismatching was associated with a significantly increased risk of grade III–IV acute GVHD. The increased risk of GVHD was offset by lower relapse, leading to similar survival (Figure 45.4). In a recent study by the Europdonor Foundation in the Netherlands, the unrelated donors' haplotypes were estimated using frequency data [99]. The presence of one or two frequent haplotypes was associated with a statistically significantly lower risk of grade II acute GVHD (HR 0.49). These observations provide evidence that haplotype-linked non-HLA variation may significantly affect transplant outcome, and that the HLA haplotype can be used as a surrogate marker for GVHD risk.

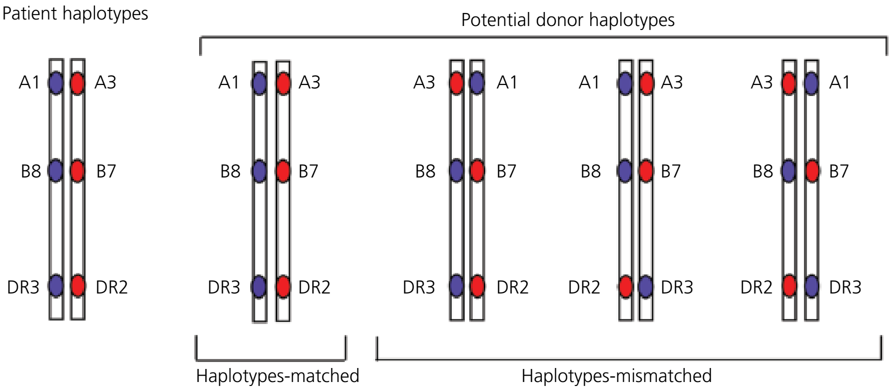

Figure 45.3 Human leukocyte antigen matched unrelated donors and recipients may be haplotype matched or haplotype mismatched [98].

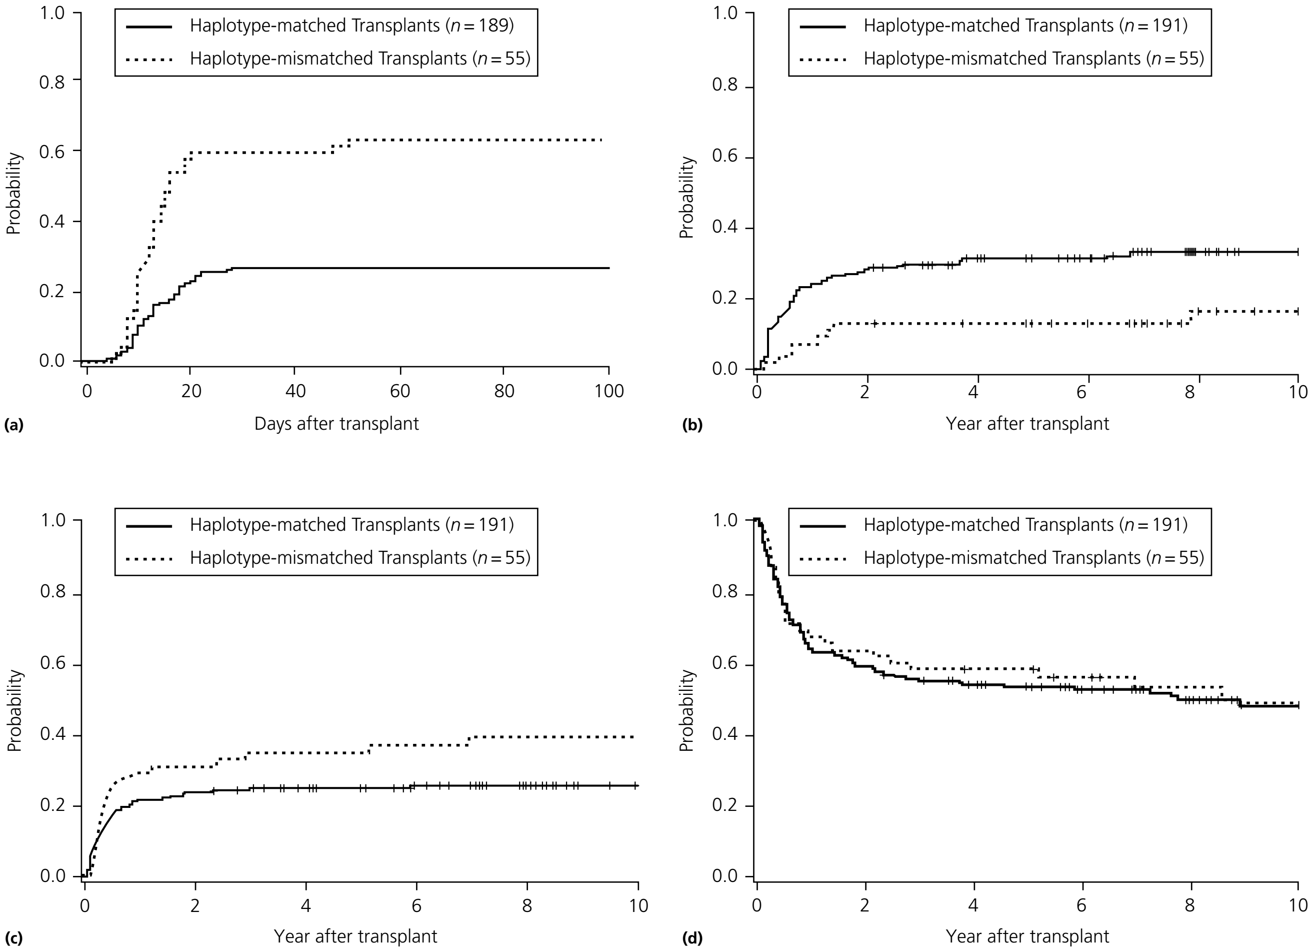

Figure 45.4 Impact of haplotype matching after human leukocyte antigen (HLA)-A, -B, -C, -DRB1, -DQB1 allele-matched unrelated donor hematopoietic cell transplantation. (a) Probability of grade III–IV acute graft-versus-host disease. (b) Probability of relapse. (c) Probability of transplant-related mortality. (d) Probability of survival. Undetected variation within the MHC may produce effects through patient–donor mismatching and/or the presence of specific variation. The JMDP surveyed a 9 Mb region of the MHC with SNPs to identify the degree of sequence conservation of three common Japanese haplotypes in a large cohort of unrelated donor–recipient pairs [69]. The presence of certain HLA haplotypes was associated with higher risks than others. A follow-up analysis of risks associated with specific SNPs has recently been carried out and is described later [70]. In the North American experience, two SNP markers were validated in 10/10 matched unrelated donor transplants [100]. A class I SNP residing close to the POU5F1 genetic locus was a marker for survival, whereas a second SNP telomeric to the HLA-DPB1 3′ untranslated region was a marker for acute GVHD. SNP genotyping of patients with two or more 10/10 matched unrelated donors revealed that most patients have a choice of donors with favorable SNPs at these two positions. These data suggest that prospective donor evaluation for MHC SNPs may help to lower risks to patients in the future.

KIR

The role of NK cells in the immunobiology of transplantation provides new avenues for optimizing allogeneic transplantation [101]. The majority of the data for NK in clinical transplantation are derived from the haploidentical related transplant experience (see Chapter 44). More recently, data on the role of HLA ligand–KIR interactions in unrelated donor HCT have demonstrated lower post-transplant disease recurrence in selected populations of mismatched transplants. These discoveries open the potential for integrating recipient ligand and donor KIR information into donor selection to fully maximize NK-mediated antitumor effects. That the HLA and KIR genetic systems segregate independently by classical Mendelian genetics has implications for HLA-matched and HLA-mismatched, related and unrelated donor HCT. The reader is referred to a comprehensive review of the NK–KIR models and typing methods (Chapter 10), basic immunobiology of NK cells (Chapter 11), and of the role of NK cell alloreactivity in haploidentical related donor transplantation (Chapter 44). The following section focuses on the recent clinical observations of HLA ligand–KIR interactions in unrelated HCT.

KIR ligands

The *ligand mismatch mechanism* of NK-cell alloreactivity is operational when there is an HLA class I disparity between the transplant recipient and donor. In unrelated donor HCT, the impact of ligand mismatching depends on disease diagnosis (lymphoid vs. myeloid), the conditioning regimen, the use of pretransplant antithymocyte globulin or ex vivo T-cell depletion methods [67,102–112] (Table 45.2). A recent study measured risks after T-cell-replete HCT for ALL, AML, MDS, and CML in three groups of donor–recipient pairs: HLA class I antigen matched (KIR ligand matched); class I antigen mismatched but KIR ligand matched, and HLA class I and inhibitory KIR ligand mismatched [111]. The 1-year survival for these three groups was 59%, 49%, and 30%, respectively. The mismatched groups had lower survival and event-free survival compared with the matched group; further, the group with both HLA and KIR mismatching had higher relapse and TRM than the other groups. A detrimental effect was observed for patients who lacked inhibitory KIR receptors; among HLA-matched cases, those who lacked the C1 or C2 ligand had lower survival compared with patients with either present. Patients who lacked C1 or C2 had higher TRM compared with patients who had all ligands present. These data suggest that inhibitory KIR ligand mismatching and missing inhibitory KIR ligands confer higher risk after T-replete unrelated donor HCT.

Table 45.2 The role of KIR in unrelated donor hematopoietic cell transplantation

Model and mechanism		Clinical endpoint	References
Mismatched ligand	Due to the donor–recipient HLA class I mismatch, the recipient's target cells lack the class I allotype presentin the donor	↓ Relapse	[67,103–109,111]
Missing ligand	Despite HLA identity, host cells are missing the class I ligand to provide the inhibitory signal	↓ Relapse	[109–112]
KIR haplotypes	Number of donor B haplotypes	↓ Relapse ↓ Mortality	[123]
	Number of activating KIR genes	↓ Relapse ↑ DFS	[125]
	Number of donor KIR3DS1 genes in B haplotypes	↓ II–IV acute GVHD ↓ TRM ↓ Mortality	[124]
	Donor homozygosity for A haplotype	↑ II–IV acute GVHD	[154]
KIR genes	Presence of KIR2DS1	↓ Relapse	[126]
HLA-E	Ligand for NKG2A	↓ Acute GVHD (E*01:03)	[117,118]
		↓ TRM ↓ Mortality	[119,120,127]
		No effect	[121]
MICA	Ligand for NKG2D		
	Patient–donor mismatching	↑ II–IV acute GVHD (GI)	[115]
		No effect	[116]

KIR, natural killer immunoglobulin-like receptor; DFS, disease-free survival; GVHD, graft-versus-host disease; TRM, transplant-related mortality; GI, gastrointestinal.

KIR-ligand mismatching had adverse effects on acute GVHD and rejection and no survival benefit for patients undergoing T-replete unrelated HCT in an analysis of 1790 transplants by the JMDP [67]. This study demonstrates an important role for HLA-C, -DPB1, KIR ligand mismatching on post-transplant relapse. Namely, donor–recipient HLA-C disparity was associated with reduced relapse among patients with ALL. HLA-DPB1 mismatches were associated with lower relapse among CML transplants. Mismatching for the KIR2DL ligand was associated with an increased risk of relapse for ALL. An increased risk of rejection was observed for KIR2DL ligand mismatches in the host-versus-graft vector. The risk of acute GVHD was increased with disparity for HLA-A, -B, -C, -DPB1, and KIR ligand mismatching in the GVHD vector; mismatching for HLA-A, -B, -DQB1, and KIR ligand in the GVH vector increased mortality.

When a recipient and donor are HLA matched, the recipient may lack the appropriate ligand for donor KIR receptor. This *missing recipient ligand* mechanism is also present between HLA-mismatched individuals, and therefore the lack of ligand is independent of donor–recipient HLA match status (see Chapter 10; Table 45.2). Missing ligand in the recipient has been associated with improved outcome after unrelated donor HCT [109,112]. Risks associated with missing recipient ligand and donor–recipient mismatched ligand were evaluated in patients who received T-replete BM or PBPCs after high-dose conditioning from either HLA-matched or HLA-mismatched unrelated donors [109]. Among HLA-mismatched recipients, the presence of homozygosity for HLA-Bw6 and C1 or C2 (missing ligand) was associated with a decreased hazard of relapse. Most of the protective effect was contributed by the subset of patients who were missing C2 or Bw4. The impact of missing ligand was most pronounced in patients with AML, CML, and ALL, and the effect was observed among HLA-mismatched and not HLA-matched transplants. Among HLA-B- and/or HLA-C-mismatched pairs, there was no difference between ligand-mismatched and ligand-matched cases. There was a trend for lower relapse among patients who were missing ligand compared with patients with ligands present. Taken together, these data indicate that missing ligand in the recipient is a useful indicator for lowered risk of post-transplant relapse.

The missing ligand model was tested in a large dataset of unrelated donor transplants for CML, AML, MDS, and ALL facilitated by the NMDP [112]. When compared with patients with all ligands present, patients who were missing one or more ligands had lower post-transplant disease relapse. Among the subset of good-risk CML patients, missing recipient ligand was an independent risk factor for clinically severe grade III–IV acute GVHD, indicating that NK-cell alloreactivity may play an indirect role in the pathogenesis of GVHD.

Recent analysis of C2 homozygosity in patients reveals different survival outcomes depending on whether the stem cell source was PBPCs (lower progress-free survival) or BM (improved survival) [113].

The highly polymorphic MICA locus in the class I region has been the subject of several new analyses concerning its role as a ligand for the activating NKG2D receptor [114–116]. Patient homozygosity for a valine at MICA residue 129 correlated with chronic GVHD risk in sibling donor HCT [114] but has thus far not been confirmed in unrelated donor HCT. Patient–donor mismatching at MICA was associated with an increased risk of grades II–IV acute GVHD particularly of the gastrointestinal tract after HLA matched and mismatched unrelated donor HCT [115]. The negative effect of MICA mismatching was independent of HLA-B or -C mismatching, two loci that display strong positive LD with MICA. The most commonly observed MICA allele, 008, did not impact transplant outcome. Different observations were made in an independent study of MICA after 12/12 matched unrelated donor HCT [116]. Among MICA*008-positive patients, there was a trend for less acute GVHD. Among 8/8 patient–donor transplants, GVHD risk did not depend on the specific HLA-B alleles present in the patient. A role for MICA in unrelated donor HCT remains to be elucidated.

In addition to MICA, the non-classical class I locus HLA-E may play a role in HCT. HLA-E is a ligand for the inhibitory NK cell receptor NKG2A. A protective effect of E*01:03 on acute GVHD [117,118] and lower TRM with improved survival [119,120] are reported in some studies, but not others [121]. Patient–donor mismatching for the HLA-E rs1264457 arginine/glycine residue 128 lowers survival [70].

KIR haplotypes and receptors

The specific genes that comprise KIR haplotypes content and their alleles may affect transplant outcome [110,122]. A higher number of donor B haplotypes is associated with lower relapse and improved survival in patients with AML but not ALL [123]. The protective effects were observed most strikingly with donors having two or more B haplotype-associated genes, and did not depend on coexisting HLA mismatching. The specific content of B haplotypes is also informative for outcome [124]. The higher the number of donor KIR3DS1 genes, the lower the risk of grades II–IV acute GVHD, TRM, and mortality after HCT from T-replete HLA-matched or -mismatched unrelated donors. These gene dose-related effects stemmed mainly from KIR3DS1, rather than B haplotype-associated polymorphisms, as GVHD risk was lower in B haplotype-positive recipients the effect of which was weaker than that from KIR3DS1.

The number of activating KIR genes has also been shown to influence risks of relapse and disease-free survival [125]. Transplantation from donors with group A KIR haplotypes or donors with lower numbers of activating KIR genes was associated with reduced relapse and improved DFS among AML/MDS recipients and to lesser extent among CML patients. There were no haplotype effects observed in patients with ALL. These data suggest that not only is the HLA ligand an important factor, but also the composition of donor KIR haplotypes may influence the risk of relapse and DFS. Use of donors with fewer activating KIR genes or with group A haplotypes, is associated with improved outcomes with respect to lower relapse and higher DFS for transplantation for AML or MDS.

Relapse after unrelated donor HCT for AML is lower when the unrelated donor carries KIR2DS1 and is not C2 homozygous [126], suggesting that the NK effects on leukemic relapse and possibly GVHD, are affected by the patient's and donor's KIR ligands, their KIR haplotypes, and specific KIR genes. Knowledge of both KIR ligands and receptors may be important in predicting suitable donors for transplantation; C1C2-positive patients receiving transplants from KIR2DS2-positive donors had lower risk of II–IV acute GVHD [127]. Finally, the level of KIR gene expression, in particular KIR2DS4, may also provide new information [128].

Cytokine and immune response gene variation

GVHD arises as a consequence of donor T-cell-mediated recognition of recipient HLAs not shared by the donor, and/or recognition of minor histocompatibility determinants. Additionally, the lack of donor inhibition of NK-cell KIRs may lead to lower GVHD risk, either because the donor and recipient differ for class I or because the recipient is missing the HLA ligand for which the donor has an inhibitory receptor. The activation of T-cell and NK-cell pathways that lead to GVHD is mediated by cytokines [129]. The activation of NK cells by immature dendritic cells in the periphery is facilitated by interleukin (IL)-2, IL-12, IL-15, and IL-18, and NK-cell cytotoxicity can be induced by TNF produced by dendritic cells. In lymphoid tissues, the IL-2- and IL-12-induced activation of NK cells leads to granulocyte–macrophage colony-stimulating factor and interferon-gamma (IFN-γ) production; these events induce T helper (Th) cell differentiation, notably polarization of Th1 cells. The intensity of tissue injury and inflammation of GVHD may be modulated through the effects of allelic diversity within the coding and promoter regions of cytokine and immune response genes [130]. Polymorphisms located in the 5′ and 3′ regulatory sequences influence transcription and cytokine serum levels, and may play a role in the release of cytokines during the three classical phases of the GVHD pathway. Recipient genetic variation for cytokine genes is hypothesized to exert its effect during the peritransplant period, when direct tissue injury from chemotherapy and radiation therapy initiates the activation of the cytokine storm; both recipient and donor genetic variation is hypothesized to modulate the severity of inflammation in the GVHD process.

The events that lead to clinical GVHD are classically described in three stages [129]. The inciting injury begins as early as the conditioning regimen when irradiation and chemotherapy directly damage host tissues and cause the release of the proinflammatory cytokine TNF-α. TNF-α serum levels peak during the conditioning regimen and correlate with increased risk of death (see later). The inflammatory environment promotes increased expression of HLA and minor histocompatibility antigens, recognition of which by donor T cells leads to the expansion of donor T-cell clones. This response is amplified by the production of cytokines by $CD4^+$ and $CD8^+$ T cells. Further augmentation of injury of host tissues from donor T cells ensues. The cytokines implicated in this phase include IL-1, IL-2, IL-8, and IL-10 [129]. The severity of GVHD may be further increased or diminished through the effects of INF-γ, and Th1 and Th2 cytokines, in particular IL-1, IL-2, IL-8, and IL-10. The final phase is characterized by cytotoxic T-cell-mediated tissue destruction.

Most of the published literature on cytokine and immune response genes has examined the effects of polymorphism of single genes after HLA-matched sibling donor HCT, with TNF-α and IL-10 being the two best studied genes. Data in unrelated donor HCT continue to emerge [131–133]. Since the distribution of cytokine gene and immune response gene variation differs worldwide, the racial and ethnic background of the study population is an important feature. This section will review the current literature that supports the hypothesis that genetic variation of selected cytokine and immune response genes modulates risks of GVHD and mortality after unrelated HCT (Table 45.3). The literature on

Table 45.3 Summary of studies of cytokine and immune response gene polymorphisms in unrelated donor HCT

Gene	Polymorphism	Model	Endpoint	Reference
CTLA4	CTLA4-CT60 (rs3087243 A/G)	Donor GG genotype	↓ III–IV aGVHD	[70]
		Patient genotype GG	↑ III–IV aGVHD	[140]
HPSE (Heparanase gene)	Rs4364254 C/T	Donor dominant model	↑ II–IV aGVHD	[140]
	Rs4693608 and rs4364254	Patient genotype	↑ II–IV, III–IV aGVHD	[144]
HSP70hom (Heat shock protein A1L gene)	2763G/A	Patient AA genotype	↑ II–IV aGVHD	[145]
IL1A	Rs1800587 (-889C/T)	Donor or patient genotype	n.s.	[137]
			↑ Survival	[155]

IL1B	Rs16944 (IL1B-511T/C)	Donor and recipient T genotype	AA ↓ aGVHD GG ↑ aGVHD ↑ Survival ↓ TRM	[155]
IL2	Rs2069762 (IL2-330T/G)	Donor genotype dominant model	↑ III–IV aGVHD	[140]
		Patient genotype G	↑ II–IV aGVHD	[138,155]
			↑ cGVHD (GT)	[70]
IL6	Rs1800795 C/G	Donor allele, recessive	↑ II–IV aGVHD	[140]
	-1082, -1064			[134]
IL10	-1082/-819/-592 Haplotype	R2 long allele G-C-C Donor	↓ TRM	[133]
		C-C-G/A Donor	n.s.	[70]
	Rs1800871 (-819); Rs1800896 (-1082); Rs1800872 (-592)		n.s.	[70]
	Levels			[139]
IL17	Rs2275913 (-197A/G)	Donor A genotype	↑ aGVHD	[146]
IL18	-137/-607/-656 haplotype	Patient haplotype (GCG)	↓ TRM ↑ OS	[142]
	Levels			[143]
IL23R	A1142A/G (Gln381Arg)	Donor genotype G (Arg)	↓ II–IV aGVHD ↑ III–IV aGVHD	[147]
			↓ aGVHD	[148]
	Rs6687620	Donor genotype	↓ II–IV aGVHD	[149]
			n.s.	[70]
	Rs11209026		n.s.	[140]
MTHFR (Methylenetetrahydrofolate reductase)	C677T	Patient T genotype	↓ aGVHD	[150]
		Donor genotype	n.s.	[151]
			n.s.	[70]
	A1298C	Patient C genotype	↑ aGVHD	[150]
NOD2	“SNP13”	Donor genotype	↑ III–IV aGVHD ↓ OS	[152,153]
	Rs17313265 Rs1077862 Rs1861757 Rs1861759 Rs6500328 Rs2111234 Rs211235 Rs7203344 Rs17313265		n.s.	[70]
			n.s.	[148,149]
TNF	Rs1799964 (-1031)	Mismatch	↑ IV aGVHD	[70]
		Patient C genotype	↑ III–IV aGVHD	[136]
		C genotype	↑ TRM	[133]
			n.s.	[140]
	Rs1800630 (-863) d4/d4	Patient genotype	↑ III–IV aGVHD	[136]
	D4/d5 microsatellite	Donor alleles	↑ Mortality	[73]
	-1031/-863/-857 (rs1799724) alleles	Patient and donor U02/U03 alleles	GVHD Relapse	[132]
				[131–135]
TNFR2	Rs1061622 (TNFRSF1B; residue Met196Arg)	Donor arginine (Arg) genotype	↑ III–IV aGVHD	[132]
			n.s.	[140]

aGVHD, acute graft-versus-host disease; cGVHD, chronic GVHD; n.s., not significant; TRM, transplant-related mortality.

cytokine gene and immune response gene polymorphisms in related donor transplantation is vast, and the reader is referred to outstanding comprehensive reviews on this topic [129,130].

Phase I: injury of host tissues and the initiation of the cytokine storm

In this phase, the skin, liver, and gastrointestinal tract of the recipient are the target organs of injury. The proinflammatory cytokines TNF-α and IL-1, together with the anti-inflammatory cytokine IL-10, are among the first to participate in the cytokine storm. TNF-α (chromosome 6p21.3) plays a multifaceted role in the pathogenesis of GVHD. TNF-α is produced by macrophages, monocytes, NK cells, and T cells, and functions as a Th1 cytokine by inducing apoptosis in target tissues and increased expression of HLA alloantigens, as well as by promoting further production of the IL-1, IL-6, and IL-10 cytokines [129]. The TNF-α and lymphotoxin-α genes are encoded within the HLA class III region, and are in strong positive LD with HLA [73,130]. The TNF promoter has extensive SNP diversity at positions -1031, -863, -857, -376, -308, -238, the most extensively studied polymorphisms of which are -308G/A and -863C/A. TNF-α variation is associated GVHD, TRM, and survival [131–134]. A role for TNF-α levels with grade III–IV acute GVHD [135] as well as the presence of arginine or methionine at residue 196 in the TNFRII receptor (chromosome 1p36) have been described [132]. More recently, SNP genotyping in discovery/validation cohorts have clarified the role of TNF haplotypes [70,73,136].

The IL-1 gene family (chromosome 2q14) consists of IL-1A, IL-1B, and the IL-1 receptor agonist. IL-1A is an intracellular regulator, and the IL-1A promoter has a C/T SNP at -899 which alters gene transcription and expression. The IL-1A -889T SNP in both unrelated donors and patients was associated with improved 1-year survival in one study [137]. The IL-1B gene encodes an extracellular protein. The IL-1B promoter has a T/C SNP at -511, and the T allele is associated with increased binding of transcription initiation factors. In a single-center study of unrelated transplant recipients, the presence of the -511T allele in the recipient and/or donor was associated with a significantly reduced risk of mortality and TRM that was independent of GVHD [138].

IL-10 (chromosome 1q31–q32) is a Th2 cytokine and a member of the IFN receptor superfamily. IL10 is anti-inflammatory, reduces HLA expression, lowers CTL recognition of HLA, and strongly inhibits TNF-α, IL-1A, IL-1B, IL-6, IL-12, and IFN-γ. The IL-10 promoter has several polymorphic positions (-3575, -2763, -1082, -1064, -819, and -592), of which the -1082A allele is associated with lower in vitro IL-10 production. In this way, IL-10 influences risks of acute and chronic GVHD. Most studies of IL-10 variation in allogeneic HCT have defined an inverse relationship between IL-10 levels and risk of acute GVHD; high IL-10 levels, or the presence of genetic variants associated with high production of IL-10, correlate with lower incidence of GVHD and mortality, consistent with anti-inflammatory protective effects. Recipient homozygosity for the -592AA promoter genotype was associated with decreased risk of severe acute GVHD and death after unrelated HCT [139], and may be a result of increased IL-10 production associated with the -592A/C and A/A genotypes. These data suggest that the antigen-presenting cells of recipients homozygous for AA are high IL-10 producers capable of inducing tolerance in donor T cells. In unrelated HCT, GVHD and mortality risk have been reported with -1082 and -1064 [134], confirming the role of IL-10 originally observed in sibling transplantation [140].

Phase II: activation of donor T cells

In this phase, donor T-cell recognition of host MHCs and minor antigens leads to T-cell proliferation and differentiation. Several pathways contribute to the activation of T cells in this phase. Th1 responses amplify the effects of the cytokine storm and involve INF-γ, IL-2, IL-12, and IL-18. Th2 responses are mediated by IL-10, IL-4, and IL-18. Data in unrelated donor HCT are currently available on the impact of genetic variation of INF-γ, IL-2, and IL-18 on GVHD.

IL-2 is a proinflammatory cytokine on 4q26. The promoter -330T/G SNP is associated with early and sustained production. Recipients encoding the IL-2 -330G allele had an increased risk of acute GVHD, and the presence of at least one G allele was associated with a twofold increase in risk of acute GVHD [138]. IL-18 (11q22) is produced by macrophages, T cells, dendritic cells, and keratinocytes and regulates both Th1 and Th2 responses and induces the secretion of growth factors in murine models [129]. As a Th1-inducing cytokine, it reduces the severity of acute GVHD when given after high-dose conditioning. When administered to the donor, IL-18 reduces the severity of acute GVHD as a Th2-inducing cytokine. IL-18 can preserve GVT effects after HCT [141]. The promoter -137G/ -607C/-656G haplotype was associated with lower TRM at day 100 and 1 year post-transplant, and with improved survival [142]. Patients with acute GVHD after unrelated HCT have high levels of IL-18 [143], and serum levels are reduced after successful GVHD therapy.

Phase III: inflammatory effectors

In this phase, cellular and inflammatory effectors produce the end-organ target damage that comprises the clinical GVHD phenotype. The two major cytokines that participate in this phase are TNF and IL-1. Injury of the gastrointestinal tract and skin caused by direct toxicity from the conditioning regimen and from GVHD causes leakage of bacterial toxins and byproducts. Mononuclear phagocytes are stimulated and secrete TNF and IL-1.

Novel genes and pathways with clinical significance in unrelated donor HCT

In addition to the genes and pathways involved in the three phases of acute GVHD, there have been new substantial data on CTLA4 [70,140], HSPE [140,144], HSP70hom [145], IL6 [140], IL17 [146], IL23R [147–149], MTHFR [150,151], NOD2 [152,153], Tim-3 [156], elafin [157] and REG3α [158] in unrelated donor HCT. These polymorphisms are summarized in Table 45.3.

Conclusion

The success of unrelated HCT as a curative therapy has come through innovative research in transplantation genetics and biology, the development of safer conditioning regimens, more effective GVHD preventive and therapeutic strategies, advances in the monitoring and detection of early disease recurrence, and improved supportive care of patients. The ultimate goal of individualizing treatment strategies will require a more complete understanding of the correlation between genotype and phenotype, and the impact of different transplant procedures on transplant-related toxicities and GVT effects. In the future, the optimal transplant approach for a given patient may include combined modalities of immunogenetic measures for the prevention of GVH and promotion of GVT effects, together with the use of post-transplant immunotherapy to lower risk of disease recurrence.

CHAPTER 46

Hematopoietic Cell Transplantation for Aplastic Anemia

George E. Georges and Rainer Storb
Fred Hutchinson Cancer Research Center and University of Washington, Seattle, WA, USA

Epidemiology

Aplastic anemia (AA) is a rare disease with an incidence of about 2–3 cases per million per year in the United States and Western Europe and about 4–7.4 cases per million per year in East Asia [1–3]. The gender ratio is close to 1:1, and there are two peaks of incidence in young adults (age 15–24 years) and above age 65 years. When treated with supportive care, including blood transfusions and antibiotics, only about 28% of patients are alive 2 years after diagnosis [4]. More than 50% of patients with severe aplastic anemia (SAA) may die within 6 months of diagnosis if they do not receive definitive therapy [5].

Effective therapies for AA consist of either immunosuppressive therapy (IST) with agents such as antithymocyte globulin (ATG) or allogeneic hematopoietic cell transplantation (HCT).

Clinical description

The disease is characterized by pancytopenia and marrow parenchyma that is lacking hematopoietic elements. Typically, the marrow cavities are filled with fat, and the aspirates show mainly lymphocytes, plasma cells, and fibroblasts. The differential diagnosis of a marrow aspirate with this appearance includes myelodysplastic syndrome (MDS), clonal T-cell disorders and AA associated with paroxysmal nocturnal hemoglobinuria (PNH). One of the most difficult entities to distinguish from AA is hypocellular myelodysplasia (see Chapter 54), but the difference is important as the two disease entities are treated differently. The conditioning regimen for HCT for MDS often contains busulfan (BU) or total body irradiation (TBI) as for acute leukemias, whereas conditioning regimens without radiation are preferred for patients with AA (see later discussion). Cytogenetic analysis of marrow is sometimes useful in distinguishing between hypocellular MDS and AA. Marrow cytogenetics are normal in AA, in contrast to MDS, and, in contrast to hypocellular myelodysplasia, developing blood cells are usually normal in appearance. Occasionally, there may be dysplastic erythroid cells in AA [6]. However, the presence of dyshematopoiesis in non-erythroid cell lines is more consistent with MDS [7].

SAA is defined as marrow cellularity less than 25% with at least two of the following:

1 absolute neutrophil count (ANC) less than 0.5×10^9/L;
2 platelet count less than 20×10^9/L; and
3 absolute reticulocyte count less than 40×10^9/L [8].

Very severe aplastic anemia (VSAA) is defined by a neutrophil count less than 0.2×10^9/L and at least one other peripheral blood criterion of SAA and marrow features consistent with SAA [9].

Etiology

Aplastic anemia may be the result of a variety of causes, including ionizing radiation, benzene, and chemotherapeutic agents [7,10,11]. Drugs causing idiosyncratic marrow injury include chloramphenicol, phenylbutazone, sulfonamides, gold, and anticonvulsants such as felbamate (reviewed in [6,7]). Rarely, AA is associated with viral diseases such as non-A, non-B, non-C hepatitis (in 5% of AA) [1,12], parvovirus (pure red cell aplasia), or Epstein–Barr virus (EBV), and autoimmune disorders such as eosinophilic fasciitis [6,7]. Some cases of AA result from congenital or hereditary disorders, including Diamond–Blackfan anemia and Fanconi anemia. A diagnosis of dyskeratosis congenita may be apparent when typical clinical features of nail dystrophy, reticulate skin pigmentation, and leukoplakia are present. Mutations in telomerase complex component (TERC and TERT) can be found in about 5% of adult patients with apparent acquired AA who lack the above clinical abnormalities and who typically show a lack or poor response to IST ("cryptic dyskeratosis congenita") [7,13,14]. In most patients, the disease etiology is unknown (idiopathic or primary AA).

Molecular and clinical biology

Possible pathophysiologic mechanisms of AA include quantitative and/or qualitative deficiencies of hematopoietic stem cells (HSCs), a defective marrow microenvironment, impairment of cellular interactions needed to sustain hematopoiesis, and immunologic suppression of marrow function. The result is a reduction in morphologically recognizable precursor cells in the marrow aspirate [15,16].

The variable response of SAA to therapy and the diverse evolution of the disease with time are perhaps a reflection of the multiple pathophysiologic mechanisms. The observation that the infusion of syngeneic marrow without prior immunosuppressive conditioning results in cure of the disease in approximately 50% of patients

suggests that a defect in hematopoietic stem cells is a likely cause in these patients [17–19]. Although most patients with AA have normally functioning stromal cells [17,18], there are a few cases where defects in the marrow microenvironment have been thought to have a role in the pathogenesis of their disease [20]. Recent evidence suggests that many cases of AA may be due to immune-mediated destruction of marrow. The immune attack leads to bone marrow failure. Furthermore, defective immune homeostasis between regulatory T cells and effector T cells plays an important role in AA. Regulatory T cells in AA appear to be intrinsically impaired, with decreased frequency, reduced cell migration capacity, and defective immunosuppression of effector cells [21]. T helper type 17 cells are increased particularly in patients with non-severe AA [22]. The responsiveness of AA to IST is evidence for the immune pathophysiology [15].

Hematopoietic cell transplantation

This chapter summarizes the results of marrow HCT for SAA over the past 40 years. Early reports of marrow HCT for SAA identified three major transplant related problems:

1 graft rejection;
2 acute graft-versus-host disease (GVHD); and
3 chronic GVHD [23–25].

The incidence of graft rejection has decreased in part because of the use of more effective immunosuppressive conditioning regimens and in part because of changes in transfusion practices (see below). The incidence of acute GVHD has also decreased owing to improved GVHD prevention protocols. The incidence and mortality of chronic GVHD may also have declined slightly. These changes, in turn, have resulted in significant improvement in survival. With longer follow-up, late sequelae, including impaired growth and development among children [26,27] and secondary malignancies [28], have become better understood.

Syngeneic grafts

Patients with syngeneic donors were among the first to receive marrow HCTs. Six of 12 patients in Seattle showed complete and sustained marrow recovery after HCT without preceding immunosuppression. In the other six patients, second marrow infusions were performed after conditioning with 200 mg/kg cyclophosphamide (CY). Ten of 12 patients were alive with an overall survival of 83% and follow-up ranging from 1.5 to 30 years [29]. The Center for International Blood and Marrow Transplant Research (CIBMTR) reviewed data on 40 syngeneic transplants worldwide. Twenty-three patients did not receive an initial conditioning regimen, and eight of the 23 had full hematologic recovery, whereas 15 required second transplants that were preceded by conditioning regimens. Twelve of 17 patients whose initial HCT was preceded by conditioning had full hematologic recovery. Four of these 17 patients died within 20 days of transplantation from pulmonary complications: fungal pneumonia, acute respiratory distress syndrome, and diffuse alveolar hemorrhage. One patient required a second transplant with conditioning for a full hematologic recovery. Although initial sustained engraftment was higher in patients who had transplants with conditioning, their 10-year survival was lower (70%) than that of patients who did not receive conditioning initially (87%) [30].

These observations suggest that syngeneic HCT can be attempted without conditioning and, if the graft fails, a second marrow infusion with a conditioning regimen is usually successful without compromising overall survival. The results of syngeneic HCTs are consistent with the concept that some cases of AA are caused by a defect in HSCs that can be corrected by simple intravenous infusion of syngeneic marrow. However, there are other cases in which the infused twin marrow HCT either fails to engraft or is rejected following a period of transient recovery of hematopoietic function. The etiology of the aplasia in these cases may be T cell mediated or be the result of unknown factors whereby the dysfunction of marrow can be overcome by conditioning with CY and a second marrow infusion [15,31].

HLA-identical related bone marrow transplantation (BMT)

The largest number of transplants for SAA performed to date have been from human leukocyte antigen (HLA)-matched sibling donors. In preparation for allogeneic HLA-identical HCT, recipients have been treated by intensive immunosuppression to prevent rejection of the grafts. Immunosuppressive agents have included CY given either alone at a dosage of 50 mg/kg/day intravenously on each of four successive days or combined with horse (or rabbit) ATG. In other patients who received earlier, less effective regimens, CY at a dosage of 60 mg/kg/day for 2 days was combined with TBI or limited field radiation (LFR), such as total lymphoid irradiation (TLI) or thoracoabdominal irradiation (TAI). Recently, some trials have decreased the CY dose and added fludarabine (FLU) with the goal of decreasing side effects related to the conditioning regimen [32]. However, these attempts at reducing the CY dose have not achieved definitively superior outcomes [33,34].

Table 46.1 summarizes recent reports on transplant outcome. The median age of patients reported in studies was approximately 19 years or less with a range of 0–69 years. The conditioning regimens and agents used for GVHD prophylaxis varied widely, even within studies. Most transplanted patients were previously transfused, a variable that has been shown to affect transplant outcome adversely by increasing the risk of graft rejection. The survival rates have improved with time in part because of decreased incidences of graft rejection, the result of changes in transfusion policies, and improved conditioning programs [29], and in part because of a decreased incidence of acute GVHD owing to the introduction of the combination of cyclosporine (CSP) and methotrexate (MTX) as GVHD prophylaxis [35,36].

Graft rejection

Graft rejection occurs because of genetic disparity between donor and recipient. Graft rejection may also be due to persistent host T cells that mediated the bone marrow failure in the first place. Two forms of graft rejection may be seen. Primary rejection is defined by the absence of any sign of hematologic function of the graft, and late rejection is defined as graft loss after initial graft function. Patients with primary or late graft rejection can often be rescued with a second HCT [37].

Graft rejection was formerly a frequent problem among patients who received CY alone for conditioning. Graft rejection at the Fred Hutchinson Cancer Research Center (FHCRC), Seattle, was seen in over 35% of patients transplanted in the early 1970s [38]. A report from the European Group for Blood and Marrow Transplantation (EBMT) showed a rejection incidence of 32% among patients transplanted before 1980 [39]. However, as described in the following section, significant progress has been made with respect to decreasing the risk of graft rejection. With most modern conditioning regimens, graft rejection has become the exception, but it is important to review the interventions necessary to prevent graft rejection.

Table 46.1 Selected recent reports of HLA-identical HCT for SAA

[b] For studies that included both HLA-identical sibling and alternative donors: MSD = HLA-identical sibling donor, UD = unrelated donor, AD = alternative donors.

[c] CY = cyclophosphamide (200 mg/kg, unless otherwise indicated); ATG = antithymocyte globulin; TBI = total body irradiation; FLU = fludarabine; Alem = alemtuzumab.
Flu + CY + ATG (Maury et al. [34]) = FLU 30 mg/m^2/day × 4 days, CY 300 mg/m^2/day × 4 days, rabbit ATG (Thymoglobulin) 3.75mg/kg/day × 4 days.
Flu + CY + ATG (Kim et al. [33]) = FLU 30 mg/m^2/day × 5 days, CY 50 mg/kg/day × 2 days, rabbit ATG (Thymoglobulin) 3 mg/kg/day × 3 days.
Flu + CY + Alem (Marsh et al. [32]) = FLU 30 mg/m^2/day × 4 days, CY 300 mg/m^2/day × 4 days, alemtuzumab total dose 40–100 mg (median, 60 mg) infused over 5 days.

[d] MTX = methotrexate; CSP = cyclosporine; PBPC = granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood progenitor cells; BM = bone marrow.

A major factor associated with graft rejection has been sensitization to histocompatibility antigens through previous blood product transfusions, as shown by extensive animal studies and confirmed in clinical trials [40–44]. Early studies reported that previously transfused patients had a significantly lower overall survival compared with untransfused patients [43], mainly because of complications of graft rejection.

Data from animal studies showed that dendritic cells in the transfusion product are important in sensitizing recipients to disparate minor histocompatibility antigens of the transfusion (and marrow) donor [45]. Treating blood products with 20 Gy of gamma irradiation *in vitro* before transfusion almost eliminated sensitization to minor histocompatibility antigens and prevented rejection of dog leukocyte antigen (DLA) identical marrow grafts [46,47]. Other methods to reduce graft rejection in the canine model included the use of platelet and red blood cell transfusions that were leukocyte depleted [42]. These data strongly suggest that all human patients with AA who are potential candidates for HCT should be given blood products that are both irradiated and leukocyte-poor [48].

In historical studies, patients with AA who proceeded to BMT without prior blood transfusion had a reduced incidence of graft rejection. However, fewer than 15% of patients were untransfused prior to transplant [43]. Other methods were therefore developed to overcome marrow graft rejection. In the 1970s, an inverse relationship was observed between the number of donor marrow cells infused and the risk of graft rejection in patients conditioned with CY [38]. A low incidence of graft rejection was seen with a high ($>3 \times 10^8$ cells/kg) marrow cell dose and vice versa. On the basis of that observation, an attempt was made to increase the number of hematopoietic cells transplanted by infusing unirradiated donor buffy coat cells in addition to the marrow [49]. Although effective in reducing the incidence of graft rejection and improving survival compared with patients given marrow alone, the infusion of donor buffy coat cells was subsequently abandoned because of the increased the risk of de novo chronic GVHD [50,51].

Historically, another approach to overcome graft rejection that was subsequently abandoned included intensifying the conditioning regimen, for example, using CY combined with TBI or LFR. Although effective in reducing the incidence of rejection, radiation-based regimens were associated with worse long-term survival due to a higher rate of transplant-related mortality (TRM) and an increased risk of secondary cancer, in addition to problems with growth, development, and fertility (see later discussion and Chapters 102, 103 and 104).

In the past decade, there was an interest in the use of granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood hematopoietic cells (G-PBHCs) as the source of HSCs for allogeneic transplantation. G-PBHCs contain an increased number of $CD34^+$ hematopoietic progenitor cells and an approximately 10-fold increased numbers of T cells compared with marrow [52]. With the infusion of a larger number of donor cells, G-PBHCs could potentially decrease the risk of graft rejection in patients with SAA. EBMT registry data indicated that approximately 38.8% of HLA-identical sibling transplants for SAA in the period 2008–2009 received G-PBHCs as the HSC source [53,54]. The use of G-PBHCs resulted in a significantly increased risk of chronic GVHD, which also significantly decreased overall survival. For patients with AA there is no compensatory benefit of a graft-versus-leukemia effect provided by PBHCs, therefore G-PBHCs should be avoided.

Animal studies showed synergistic immunosuppressive effects between ATG and alkylating agents such as procarbazine and CY as assessed by the criteria of skin graft prolongation and overcoming marrow graft rejection [55,56]. On the basis of these experimental animal data, the regimen of CY (200 mg/kg) and horse ATG was developed and was initially used to rescue patients in whom their first graft had been rejected. Fifteen of 19 previously transplanted patients who were reconditioned with CY and ATG had successful second marrow grafts, and 50% became long-term survivors [57]. More recently, survival of patients after second HCT increased to 83% at FHCRC, a result not significantly different from survival after the first transplant [37].

Because of the success of CY (200 mg/kg) and ATG in second transplants, the combination was chosen as a conditioning regimen for first transplants from HLA-identical family members beginning in 1988. This led to the initial report of significantly improved outcome of HCT compared with the historical regimen of CY alone with buffy coat infusions [57].

Changes in transfusion policies (consistent use of irradiated, leukodepleted blood products), and improved conditioning regimens (combined CY + ATG) before transplant, have led to significant decreases in graft rejection [39]. In addition, post-grafting immunosuppression aimed at controlling GVHD may also have a role in controlling host-versus-graft (HVG) reactions. A retrospective analysis by the EBMT suggested that the use of CSP as GVHD prophylaxis decreased the rejection rate compared with MTX alone [39], but a randomized prospective study in Seattle failed to show differences in rejection when long-term MTX was compared with a short course of MTX combined with CSP [29,36]. Studies in animals showed MTX and CSP to be superior to CSP alone, not only in controlling GVHD but also in suppressing HVG reactions, thereby enhancing engraftment [58]. Hence post-grafting immunosuppression used for GVHD prevention also has to be considered when evaluating new conditioning regimens for their efficacy in decreasing the risk of graft rejection.

Updated results from the Seattle study of CY and ATG for patients with SAA confirmed that graft rejection had become a minor problem (Figure 46.1a). Of the 81 consecutive patients enrolled, 76 had received multiple transfusions and 44 had failed prior immunosuppressive therapy. The ages of the patients ranged from 2 to 63 years. After transplantation, 81 patients received MTX and CSP for GVHD prophylaxis. There was a 3.7% incidence of graft rejection between 1 and 7 months after transplantation (Figure 46.1a). Of the three patients with graft rejection, two were alive following successful second HSC transplantation. With a median follow-up of 9.2 years (range 0.5–16.4 years), the overall survival rate was 88% (Figure 46.1e) [59].

Some transplant centers have continued to use CY without ATG as the conditioning regimen for younger patients receiving marrow HCT from HLA-identical siblings. Results from a prospective randomized multicenter trial sponsored by the Gruppo Italiano Trapianti di Midollo Osseo (GITMO) and the EBMT that compared CSP alone with MTX and CSP for GVHD prophylaxis in 71 patients with SAA showed that the overall incidence of graft rejection was 8% [60]. Several factors may explain why the GITMO/EBMT results with CY conditioning alone were superior to the historical data from the Seattle group in the 1980s. Since the initial Seattle report, there has been increased awareness in the medical community of the benefit of leukodepleted and irradiated blood products for patients with SAA. Seventy of 71 patients in the GITMO/EBMT study had been transfused with a median of 6 units of blood products prior to transplantation. Although not specifically addressed in the GITMO/EBMT study, the widespread use of

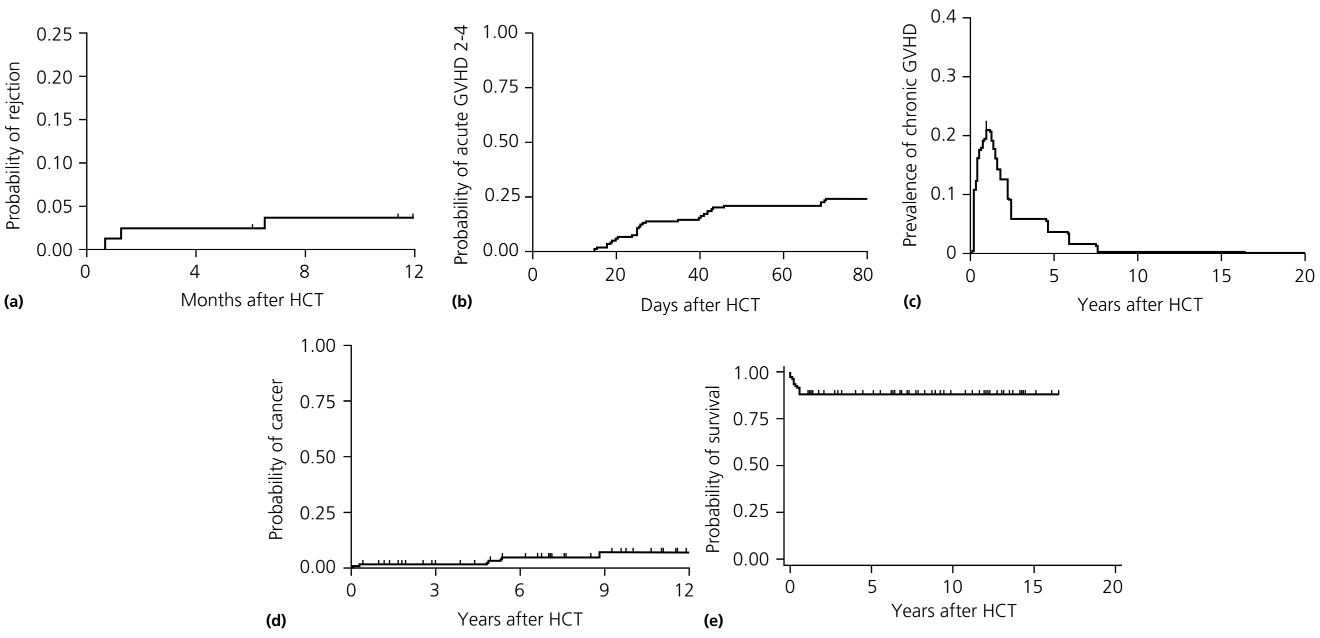

Figure 46.1 Cumulative incidences of (a) graft rejection and (b) developing acute grade II–IV graft-versus-host disease (GVHD) in 81 consecutive patients with aplastic anemia given human leukocyte antigen (HLA)-identical marrow grafts following cyclophosphamide (CY) and antithymocyte globulin (ATG) conditioning and GVHD prophylaxis with methotrexate (MTX) and cyclosporine (CSP). irradiated and leukodepleted blood products for transfusion support prior to transplantation for patients with AA may have contributed to the lower incidence of graft rejection seen since the 1980s. The GITMO/EBMT study included predominantly younger patients, most of whom were not treated with a trial of immunosuppression prior to proceeding to allogeneic HSC transplant. In contrast, the updated multicenter trial of CY and ATG included older, heavily transfused patients whose prior treatment with immunosuppressive therapy had failed [59,61].

In a multicenter prospective trial conducted over 7 years, 134 patients were randomly assigned to receive CY alone or in combination with horse ATG. The majority of patients had not received prior IST. Patients received T-cell-replete (unmodified) bone marrow from an HLA-identical sibling and GVHD prophylaxis consisted of CSP and MTX. The 5-year probabilities of survival were 74 and 80% in the CY and the CY–ATG groups, respectively. Graft failure rates were similar at 18 and 16%, respectively. Fifteen of 22 patients with graft failure underwent a second HCT from their initial donor, but three patients in the CY alone group required more than two transplantations. At the last follow-up, 12 of the 22 patients with graft failure were alive. Unfortunately, this randomized study was underpowered to detect a statistically significant difference in survival, so the data are inconclusive as to whether the combination of CY plus ATG leads to superior outcome after BMT [62].

Perhaps for younger patients (under 20 years of age) who have not received prior IST for AA and who received only a very limited number of blood product transfusions, all which were irradiated and leukodepleted, the risk of graft rejection following HLA-identical sibling BMT is low and the addition of ATG to the CY conditioning regimen may not be necessary. However, some data indicate that transplantation of a high cell dose of donor marrow (corrected for donor peripheral blood cell content) results in significantly increased risk of chronic GVHD [59]. Therefore, to avoid possible graft rejection when the marrow cell dose is restricted, ATG should be administered with CY.

The addition of FLU to a reduced dose of CY with ATG has been evaluated as an alternative approach to overcoming graft rejection. However, studies of FLU–CY–ATG were confounded by the use of G-PBHC instead of bone marrow to help overcome the risk of graft rejection. The incidence of graft rejection was relatively low, but the incidence of severe acute GVHD was high, and the overall outcome was not superior to the accepted standard CY (200 mg/kg)–ATG regimen [34,63–65]. A recently completed randomized study compared FLU (120 mg/m^2), CY (100 mg/kg), and rabbit ATG (9 mg/kg) with CY (200 mg/kg) and rabbit ATG [33]. There was no significant difference in combined primary and secondary graft rejection in the two arms (13.4 vs. 16.8%, respectively), or the incidence of acute or chronic GVHD and overall survival. However, there was a lower incidence of pulmonary toxicity among recipients of HLA-matched sibling grafts in the FLU–CY–ATG arm. This study was confounded by relatively small number of patients, inclusion of patients with the diagnosis of hypoplastic myelodysplastic syndrome, use of alternative donors, and use of G-PBHC. Furthermore, pulmonary toxicity was not observed in the Seattle series of patients given the CY(200 mg/kg)–ATG regimen [59]. Nonetheless, the data suggest that FLU 120 mg/m^2 may be potential substitute for up to 100mg/kg of the CY dose. Since FLU has some non-overlapping toxicity with CY, the FLU–CY combination may be beneficial particularly in older patients who may have an increased risk of cardiac or pulmonary toxicity from high-dose CY. However, to date, there is no definitive evidence of a survival benefit in patients receiving the combined reduced-intensity FLU–CY–ATG regimen compared with the standard-dose CY–ATG. Although reduction of the CY dose with addition of FLU may be a reasonable option for HCT in patients older than 40 years of age, additional studies are needed to confirm this recommendation.

Other centers have evaluated the combination of FLU (120 mg/m^2) and CY (1200 mg/m^2) with alemtuzumab (40–100 mg) as an alternative conditioning regimen [32]. The report of 50 patients with AA treated with the FLU–CY–alemtuzumab regimen was limited owing to several factors such as: inclusion of patients with non-severe aplastic anemia, wide variation in the dose of alemtuzumab, less than half of the patients received unmodified bone marrow as the hematopoietic cell source, and the inclusion of alternative donors. The incidence of graft rejection was relatively high at 12%, and there were infectious complications after transplant, including cytomegalovirus (CMV), adenovirus, and EBV [32]. Altemtuzumab-containing regimens may be considered as an alternative to ATG for patients who are not able to tolerate ATG due to prior exposure to ATG treatment or who have anti-ATG antibodies detected [66]. The combined FLU plus reduced-dose CY (with either ATG or alemtuzumab) appears to be an alternative conditioning regimen suitable for older patients, but owing to the apparent increased risk of graft rejection the reduced-dose alternative regimens are not recommended for patients who can tolerate the standard CY (200 mg/m^2)–ATG Seattle regimen.

In summary, results from clinical trials to date indicate that combined CY and ATG conditioning followed by MTX and CSP as post-grafting immunosuppression is the most effective and reliable regimen to prevent graft rejection and GVHD following HLA-identical BMT for SAA. Similar survival might be obtained without ATG in younger, relatively untransfused patients. The use of the least toxic transplant regimen associated with the lowest incidence of graft rejection avoids the need for having to deal with this potentially life-threatening complication after transplant. For first transplants, the use of G-CSF mobilized PBHC is not appropriate given the increased risk of chronic GVHD. Treatment guidelines for SAA include uniform adherence to the following:

1. Use irradiated and leukodepleted blood products before transplant.
2. For patients with an HLA-identical sibling donor, proceed to BMT as first-line therapy.
3. Use the well-established and well-tolerated conditioning regimen of CY (200 mg/kg) and ATG.
4. Infusion of 2.5×10^8 nucleated donor marrow cells (corrected for donor peripheral blood cell count)/kg.
5. Do not use G-CSF-mobilized peripheral blood progenitor cells.
6. Use combined MTX and CSP post-grafting immunosuppression.
7. Despite the potential increased risk of graft rejection, reduced-intensity conditioning regimens such as FLU–CY with either rabbit ATG or alemtuzumab may be considered for older patients (age >40 years) unable to tolerate CY 200 mg/kg.

Mixed donor–host hematopoietic chimerism

Transient mixed chimerism is common in patients after marrow allografts for AA. In one study, almost 60% of patients had mixed chimerism in peripheral blood or bone marrow after HCT, and two-thirds of these eventually converted to complete donor-type hematopoiesis while the remainder rejected their grafts [67]. In a larger study of 116 patients with AA transplanted from gender-mismatched HLA-identical siblings, 54% were mixed chimeras detected in either blood or marrow. Although patients with mixed chimerism appeared to have a higher incidence of graft rejection (14%) than those who were complete chimeras (9%), this difference was not statistically significant [68]. A study of 45 patients with AA who received HLA-identical sibling BMT and serial monitoring with short tandem repeat (STR) polymerase chain reaction (PCR) chimerism analysis reported that 72% developed complete donor chimerism, 11% had stable mixed chimerism, and 17% had an increase in host chimerism after transplantation. Patients with increased host chimerism after transplantation had a 50% incidence of graft failure and an overall survival of 38%. Patients with complete donor or stable mixed chimerism had superior survival. None of the patients with stable mixed chimerism developed chronic GVHD [69]. The inclusion of more intensive in vivo T-cell-depleting antibody therapy in the conditioning regimen results in a higher incidence of mixed chimerism after transplant. A recent study of FLU–CY–alemtuzumab conditioning reported that all evaluable patients had long-term, sustained mixed T-cell chimerism after HCT [32]. Among patients receiving rabbit ATG (8 mg/kg) plus CY 200 mg/kg conditioning, 80% had stable mixed hematopoietic chimerism [70]. These results suggest that monitoring chimerism after allogeneic HCT is useful for predicting the subsequent transplant outcome. T-cell chimerism is now routinely determined after HCT. Chimerism analysis is an indispensable tool for monitoring the kinetics of engraftment and the ultimate fate of the graft; it also appears to be useful in predicting impending graft rejection.

Acute graft-versus-host disease (see Chapter 83)

Once engraftment has been accomplished, acute GVHD may develop, usually within the first 6 weeks after HCT. Grade II–IV acute GVHD has an adverse effect on survival in patients transplanted for SAA. Early Seattle data showed an actuarial probability of survival at 11 years of 45% for SAA patients with preceding grade II–IV acute GVHD compared with 80% survival among patients with grade 0 and I acute GVHD [71]. Similarly, subsequent CIBMTR data showed a 31% 5-year actuarial probability of survival for SAA patients with grade II–IV acute GVHD compared with 80% among patients with no or mild acute GVHD [72]. During the 1970s, MTX was the most commonly used agent given after BMT to prevent acute GVHD, and 35% of MTX-treated SAA patients developed grade II–IV acute GVHD [71].

Because of the high mortality associated with acute GVHD, a number of studies were carried out in the 1980s to investigate whether the incidence of this complication could be reduced and survival improved. CSP was initially studied as a single agent to prevent acute GVHD. Retrospective analyses showed that CSP favorably influenced the survival of more recently transplanted SAA patients compared with historical control patients given MTX alone [73–76].

A number of transplant centers combined prednisone (PSE) and CSP in hope of improving control of acute GVHD. A randomized prospective study of patients with high-risk lymphohematopoietic malignancies showed that the combination of CSP and PSE was only marginally better than CSP alone in preventing acute GVHD, but this came at the expense of a significant increase in chronic GVHD [77,78]. Encouraging data in experimental animals led, in 1981, to the introduction in the clinic of a combination of MTX (15 mg/m^2 given at 24 hours after completion of bone marrow infusion and 10 mg/m^2 given on days 3, 6, and 11 after BMT) combined with CSP. One randomized trial from Seattle showed a significant reduction in incidence and severity of acute GVHD in 22 SAA patients given the combination versus 24 patients receiving MTX alone [36], and overall survival was higher in patients who received the combination of drugs [36,79]. Similar findings were obtained in patients with leukemia where the combination of MTX and CSP was found to be superior to CSP alone in preventing acute GVHD [80]. In a later non-randomized retrospective analysis of CIBMTR data from 595 patients with SAA who had received BMTs from matched siblings, patients who received either CSP alone or CSP with MTX compared with MTX alone had a statistically significant improved survival rate of 69% versus 56%, respectively [72]. The reduction in acute GVHD resulted in improved survival, a finding that was especially impressive among pediatric patients with SAA [73]. One retrospective analysis suggested that optimal doses of both MTX and CSP were important in controlling acute GVHD [81]. Because of the success of the combination of MTX and CSP, a randomized study was carried out to compare MTX + CSP with CSP + MTX + PSE for patients with hematologic malignancies and SAA. Among patients with HLA-identical donors, the addition of PSE increased the risk of acute and chronic GVHD unless the PSE was administered after the completion of a short course of MTX [82]. A subsequent randomized trial of MTX and CSP versus MTX, CSP and "late PSE" was completed in patients with leukemia and suggested improved survival in the MTX and CSP arm ($p = 0.1$) [83].

The prospective randomized study by GITMO/EBMT confirmed the initial Seattle report and showed that the combination of MTX and CSP resulted in superior 5-year estimated survival compared with the use of CSP alone for SAA patients transplanted with an HLA-identical sibling marrow graft. The incidence of acute GVHD in the MTX and CSP group versus CSP alone was 30 and 38%, respectively [60].

Updated results of the study with the Seattle regimen consisting of CY and ATG, HLA-identical marrow followed by combined MTX and CSP immunosuppression in 81 consecutive patients showed that the cumulative incidence of grade II–IV acute GVHD was 24% (Figure 46.1b) [59]. The severity of GVHD observed was grade II (21.6%), grade III (0%), and grade IV (2.4%). Thus, despite the greater age of patients in the Seattle regimen study compared with the GITMO/EBMT study, the overall incidence of acute GVHD was lower in the Seattle study. Similarly, the randomized CY versus CY + ATG multicenter study with MTX + CSP GVHD prophylaxis reported an acute GVHD incidence of 18 and 11%, respectively [62]. These findings suggest that the incorporation of ATG in the conditioning regimen may be effective in preventing acute GVHD, particularly in older patient age groups. ATG may have an effect on depletion of the infused donor T cells.

Several smaller studies have evaluated potential alternatives to the standard CY–horse ATG regimen. As an alternative to horse ATG, the use of rabbit ATG (total dose 8 mg/kg) in the conditioning regimen with CY 200 mg/kg and infusion of HLA-identical sibling bone marrow and post-grafting CSP + MTX in 20 SAA patients was associated with a 0% incidence of acute GVHD. However, the rabbit ATG recipients experienced a high incidence of invasive fungal infection and delayed immune recovery and overall survival was not improved compared with recipients of horse ATG [70]. In addition, there is significant variability in the methods for assessing the incidence of acute GVHD among transplant centers, which can lead to significant under-reporting of the incidence of acute GVHD in retrospective single-center studies [84]. A reduced-intensity regimen of FLU (120 mg/m^2), CY (100 mg/kg), and rabbit ATG (9 mg/kg) included post-transplant CSP and abbreviated MTX. The incidence of acute GVHD was 23%, although 70% of the patients received bone marrow and 37% received alternative donor grafts [33]. In a limited study of 30 SAA patients treated with the reduced-intensity FLU (120 mg/m^2)–CY (1200 mg/m^2)–rabbit ATG (15 mg/kg) conditioning regimen, 20 patients were transplanted with bone marrow from HLA-identical siblings and most received post-grafting CSP + MTX: there was a 10% incidence of acute GVHD [34]. A study incorporating the FLU–CY–alemtuzumab regimen used CSP alone as post-grafting immunosuppression and reported a 16% cumulative incidence of acute GVHD [32]. In summary, the use of rabbit ATG or alemtuzumab given during the conditioning regimen has the potential to decrease the risk of acute GVHD after allogeneic HCT. However, rabbit ATG and alemtuzumab have been associated with a significant risk of increased opportunistic infections such as potentially fatal invasive fungal and viral infections, hence overall survival has not been significantly improved.

Chronic graft-versus-host disease (see Chapter 84)

Whereas significant progress has been made in reducing the incidences of graft rejection and acute GVHD, chronic GVHD continues to be a major complication of marrow grafting for AA. Unlike the graft-versus-leukemia effect associated with chronic GVHD that can improve the survival of patients with leukemia, there is no benefit of chronic GVHD in patients transplanted with AA. Historically, the incidence of chronic GVHD varied depending on the patient groups studied. Studies of a few small series of children transplanted from HLA-identical siblings reported incidences of 0–25% [85–87], whereas the incidence was as high as 40–60% among other series that included adult patients and those who received supplemental buffy coat infusions [88,89]. In most current series of matched sibling transplants that included adults, the incidence of chronic GVHD was 10–30% [54,59,60,62,65,90,91] (see Table 46.1).

Early studies identified a history of acute GVHD as the most important risk factor for chronic GVHD [50,92]. Older patients also experienced more chronic GVHD. De novo chronic GVHD occurs without preceding acute GVHD. In addition to donor buffy coat infusions, other risk factors, including increased patient age and preceding corticosteroid therapy, have been associated with de novo chronic GVHD development [50,93]. More recently, infusion of high corrected marrow cell dose (greater than 3.4×10^8 cells/kg) was associated with a significantly increased incidence of chronic extensive GVHD [hazard ratio (HR) 7.7] and lower overall survival [59].

G-CSF--mobilized PBHC increases the risk of chronic GVHD, which is more protracted and less responsive to treatment compared with bone marrow [94]. Because of the excellent overall survival of SAA patients after HLA-identical BMT given combined CY + ATG conditioning and CSP + MTX GVHD prophylaxis, it is very unlikely that future studies will demonstrate any significant benefit of utilizing T-cell-depleted or CD34-enriched PBHC over HLA-identical bone marrow as stem-cell source. Therefore, for patients with SAA, HLA-identical bone marrow with a target-corrected cell dose of 2.5×10^8 nucleated cells per kilogram body weight is the optimal source of hematopoietic stem cells.

Chronic GVHD is associated with significant morbidity and requires prolonged IST, although ultimately immunosuppression can be discontinued in most patients as chronic GVHD resolves [59,95]. In the past, up to one-third of affected patients died, often from infections. PSE, azathioprine, CY, procarbazine, CSP, thalidomide, mycophenolate mofetil (MMF), tacrolimus (FK-506), and extracorporeal photopheresis given either alone or in combination have all been used for treatment of chronic GVHD (see Chapter 84) [95–100].

Recent evidence suggests that persistent chronic GVHD is a risk factor for the development of solid tumors late after transplantation. In addition, in the Seattle survey of long-term survivors after allogeneic transplantation for AA, chronic GVHD was a risk factor for development of cataracts, lung disease, bone and joint disease, and depression [101]. In the Seattle experience, since the introduction of the CY and ATG conditioning regimen and the discontinuation of added buffy coat cell infusions, the prevalence of chronic GVHD has significantly decreased. Chronic GVHD was not only less frequent but also appeared to be more responsive to therapy in patients conditioned with CY and horse ATG and given marrow alone compared with historical control patients treated with CY and marrow plus buffy coat. In the updated Seattle transplant regimen report with HLA-identical sibling marrow grafts consisting of CY and horse ATG followed with MTX and CSP, the cumulative incidence of chronic GVHD observed was 26% (Figure 46.1c). In all surviving patients, chronic GVHD responded to therapy with complete responses. Of the patients with chronic GVHD, 83% survived long term. The peak incidence of chronic GVHD was at 1 year after transplantation. By 7 years, no patients required IST for chronic GVHD [59].

The incidences of chronic GVHD in the GITMO/EBMT trial with CY conditioning and post-grafting immunosuppression with either CSP alone versus MTX + CSP were 30% and 44%, respectively. The majority of patients with chronic GVHD had limited disease of the skin; the overall incidence of extensive chronic GVHD was 9% [60]. Most of the patients in the GITMO/EBMT study were children, who had a lower incidence of chronic GVHD than adults.

Prompt diagnosis of chronic GVHD combined with aggressive initiation of IST with the combination of CSP and PSE has resulted in an apparent decrease in the time needed for inducing remission of chronic GVHD, and the overall response to treatment has improved over time. However, this improvement has not been associated with a significant increase in survival for patients with SAA who develop chronic GVHD [97,102]. Hence mortality associated with chronic GVHD remains a significant problem for patients following allogeneic HCT.

These observations suggest that improvements in the prevention of chronic GVHD must be sought to improve patient survival further. Perhaps prompt diagnosis and treatment of chronic GVHD may help improve response to treatment and overall survival. However, in a randomized prospective study comparing CSP continued at "therapeutic levels" for 24 months with 6 months after HCT for patients at highest risk of developing chronic GVHD, for example, those with preceding acute GVHD, corticosteroid therapy, and older patients, there was no difference in overall survival between the two groups [98]. In the setting of HLA-identical sibling HCT, CY + ATG conditioning and GVHD prophylaxis with MTX + CSP, the most effective means of preventing chronic GVHD may be achieved by limiting the infused donor marrow to a target cell dose of 2.5×10^8 total nucleated cells/kg (corrected for donor peripheral blood cell count). Taken together, current evidence indicates that the Seattle regimen of CY and ATG conditioning followed by HLA-identical marrow transplantation and combined MTX and CSP post-grafting immunosuppression appears to provide one of the lowest risks of graft rejection and acute and chronic GVHD compared with other transplantation regimens.

Some recent studies suggest that inclusion of rabbit ATG or alemtuzumab in the conditioning regimen may decrease the incidence of chronic GVHD. In one report, the substitution of rabbit ATG (total dose 8 mg/kg) in place of horse ATG (90 mg/kg) as part of the conditioning regimen with CY 200 mg/kg prior to HLA-identical sibling BMT was associated with a decreased incidence of chronic GVHD, 0% versus 34%, respectively. However, there was increased risk of invasive fungal disease after transplantation, earlier CMV reactivation, and delayed lymphocyte recovery in rabbit ATG recipients. Despite the decreased incidence of chronic GVHD, there was no difference in overall survival after HCT between recipients of rabbit or horse ATG [70]. Following the reduced-intensity FLU–CY–alemtuzumab conditioning regimen and CSP post-grafting immunosuppression, the cumulative incidence of chronic GVHD was 4%, despite only 48% of patients receiving bone marrow as the source of hematopoietic stem cells [32]. In both studies, nearly all evaluable patients had sustained mixed T-cell chimerism after HCT. Profound in vivo T-cell depletion with rabbit ATG or alemtuzumab has the potential to decrease the incidence of chronic GVHD. Additional studies are needed to determine if these alternative regimens can consistently reduce the incidence of chronic GVHD and also result in improved overall survival.

Interstitial pneumonia

The incidence of interstitial pneumonia occurring after transplantation in patients with SAA has decreased over time. In 1989, Weiner et al. [103] reviewed CIBMTR data from 547 patients with AA receiving HLA-identical marrow grafts for the risk of interstitial pneumonia. They found an overall incidence of interstitial pneumonia of 17%. CMV pneumonia affected 37% of patients, 22% had pneumonia from other organisms, and in 41% of cases no organisms were identified. The case fatality rate was 64%. At that time, four factors predicted the development of interstitial pneumonia:

1 the use of MTX rather than CSP after HCT;
2 moderate to severe acute GVHD;
3 TBI compared with CY in the preparative regimen; and
4 increased patient age.

Results from 329 patients treated for SAA in Seattle from 1974 to 1990 showed that the overall incidence of interstitial pneumonia was 16%. Some 44% of affected patients had CMV pneumonia, 37% had pneumonia resulting from a variety of other infectious organisms, and 19% had pneumonia of unknown etiology. The overall mortality was 7%. TBI and acute GVHD were significant risk factors for the development of interstitial pneumonia, but there was no adverse influence of patient age or of MTX prophylaxis on the development of interstitial pneumonia [29]. More recent studies confirmed that grade II–IV acute GVHD was the major risk factor for the development of interstitial pneumonitis [104]. A study of idiopathic lung disease after transplant found that patients with AA conditioned with CY had a significantly lower incidence (less than 5%) than those transplanted for malignant diseases who were conditioned with TBI or BU-containing regimens [105]. The case mortality rate for these studies and more recent Seattle data, all of which contained large numbers of patients with malignant diseases, was 71–75% [104–106]. Over time, avoidance of TBI, improved prophylaxis for acute GVHD with MTX and CSP, and improved supportive care, including the prompt diagnosis and treatment of infectious agents such as CMV (by DNA detection methods), have all contributed to the decreased incidence of idiopathic interstitial pneumonitis. In the subsequent update of the patients with SAA treated with the Seattle regimen, only one of 81 patients died of idiopathic interstitial pneumonia [59].

Survival

Overall survival following HCT for SAA has increased steadily over the last 40 years. During the 1970s, survival rates of 40–60% were commonly seen, whereas the survival rates now range from 74 to 100% [54,59,60,62,64,65,90,91,107–111] (see Table 46.1). In Seattle, we observed improved 5-year overall survival among patients transplanted after July 1988 (88%) compared with patients transplanted before 1977 (41%) and compared with patients transplanted between 1977 and 1988 (61%). All patients transplanted since 1985 received MTX and CSP for GVHD prophylaxis, and since 1988 all were conditioned with CY and ATG rather than CY alone. Updated results employing the Seattle transplant regimen (CY and ATG conditioning, HLA-identical marrow HCT with combined MTX and CSP post-grafting immunosuppression) confirmed that with a median follow-up of 9.2 years (range 0.5–16.4 years), the survival rate was 88% [59]. In this study of 81 consecutive SAA patients, the median age was 25 years (range 2–63 years) (Figure 46.1e).

The Seattle group recently reported updated results for 148 consecutive children (median age 12.8 years) with SAA who received HLA-matched related bone marrow grafts between 1971 and 2010 (Figure 46.2) [111]. Patients were divided into three groups reflecting changes in the conditioning and GVHD prophylaxis regimens that occurred over time. Patients in Group 1 (Figure 46.2a) were conditioned with CY 200 mg/kg followed by "long" (day 102) MTX. Patients in Groups 2 and 3 received CY alone (Figure 46.2b) or CY with horse ATG (Figure 46.2c), followed by "short" (days 1, 3, 6, 11) MTX and CSP (until day 180). With a median follow-up of 25 years, the 5-year survivals were 66, 95, and 100% for Groups 1, 2, and 3, respectively (overall $p < 0.0001$). The 3-year estimates of graft rejection were 22, 32 and 7, respectively. The probabilities of grades III and IV acute and 2-year chronic GVHD were 15, 0, and 3% and 21, 21, and 10%, respectively. In summary, as outlined in the sections above, advances in the preparative and GVHD prophylaxis regimens and supportive care in the past 40 years have led to improved outcomes for children with SAA. The results confirm the use of allogeneic marrow transplantation as first-line therapy for children who have HLA-matched related donors [111].

The randomized GITMO/EBMT trial comparing CSP alone with combined MTX and CSP for patients conditioned with CY alone showed estimated 5-year survival of 94% for the MTX and CSP group and 78% for the CSP alone group [60]. The difference in survival between the two groups was statistically significant. This study confirmed the initial Seattle results demonstrating the superiority of combined MTX and CSP post-grafting immunosuppression. The multicenter randomized study of CY versus CY + ATG showed that the 5-year survival was 74% for the CY alone group and 80% for the CY + ATG group [62].

Analysis of transplant registry data has been helpful in identifying important trends influencing survival over time. The reported results are in general less favorable than the optimal conditioning regimens reported by some transplant centers because multiple conditioning and GVHD prophylaxis regimens are used by registry members, some of which were suboptimal. A retrospective multicenter multiregimen CIBMTR study reported that 5-year survival after HLA-identical sibling transplants had increased from 48% in 1976–1980 to 66% in 1988–1992 [89]. Because of the introduction of CSP for GVHD prophylaxis, the risk of GVHD decreased. Improved long-term survival was because of decreased mortality in the first 3 months post-transplant. The incidence of reported graft failure did not change significantly, ranging from 20% in 1976–1980 to 16% in 1988–1992. However, only 9% of reported transplants in 1988–1992 included CY and ATG conditioning.

CIBMTR data for 1699 patients receiving HLA-identical sibling transplants for SAA between 1991 and 1997 showed a 5-year probability of survival (± 95% confidence interval) of 75 ± 3% for 874 patients less than 20 years of age, 68 ± 4% for 696 who were 21–39 years old, and 35 ± 18% for 129 who were 40 years or older [112]. Survival was highest in untransfused patients transplanted early in the course of their disease and who were without active infection at the time of transplant. Only a minority of patients reported to the registry between 1991 and 1997 received CY and ATG conditioning with combined MTX and CSP post-grafting immunosuppression. More recently, since children with HLA-identical siblings were increasingly referred for transplantation as first-line therapy, and

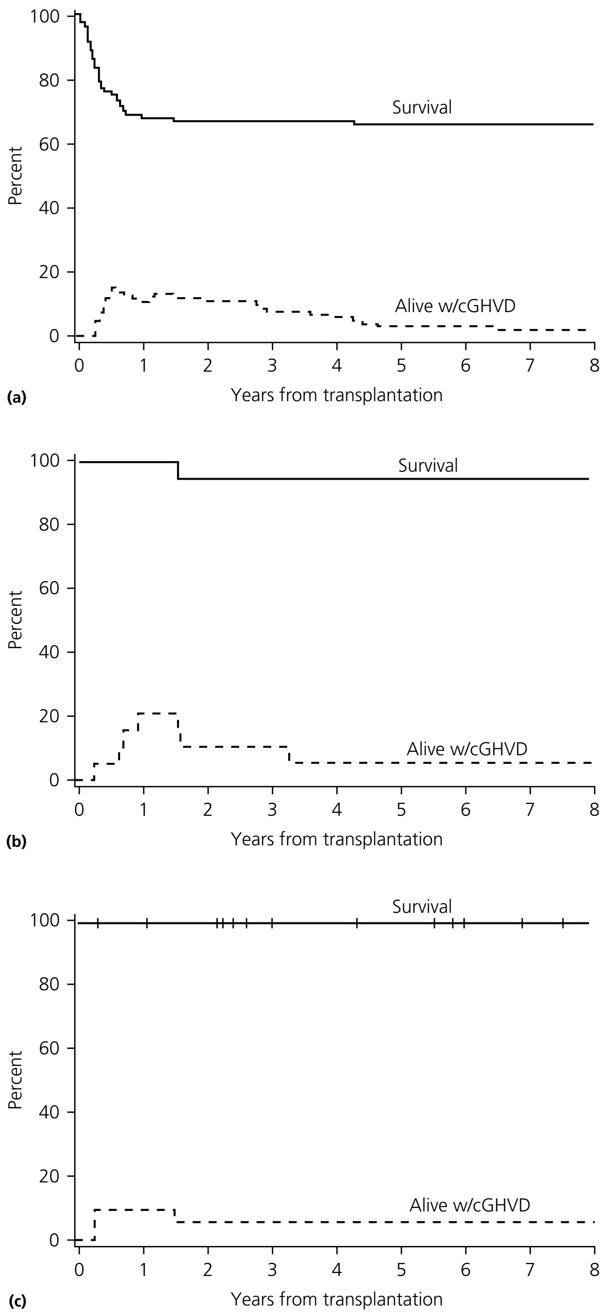

Figure 46.2 Survival (upper curves) and prevalence of chronic graft-versus-host disease (cGVHD, lower curves) among pediatric patients in Seattle with severe aplastic anemia that received an allogeneic bone marrow transplant (BMT) from an HLA-identical sibling over three time periods, (a) Group 1, BMT between 1971 and 1984: cyclophosphamide (CY) 200 mg/kg conditioning and post-transplant GVHD prophylaxis with methotrexate (MTX) only ($n = 98$). (b) Group 2, BMT between 1981 and 1988: CY conditioning with MTX + cyclosporine (CSP) ($n = 19$). (c) Group 3, BMT between 1989 and 2010: CY + anti-thymocyte globulin (horse ATG) conditioning, MTX + CSP GVHD prophylaxis ($n = 31$). Source: Burroughs et al. 2012 [111]. Reproduced with permission of John Wiley & Sons, Ltd.

because the majority of transplant centers now administered CY + ATG conditioning with MTX + CSP for GVHD prophylaxis, the survival trends have continued to improve. Between 1995 and 2003, 305 patients aged 20 years and under who received bone marrow as the HSC source had a 5-year probability of survival of 85%. The 253 patients more than 20 years old had a 5-year survival of 64%. Survival was significantly worse for the 134 patients who received G-PBHC as the graft source owing to the increased incidence and severity of chronic GVHD [54].

EBMT data for 1275 patients receiving HLA-identical sibling transplantation between 1991 and 2002 confirmed and extended the CIBMTR results. The year of the transplant, the age of the patient, and the interval from diagnosis to transplant predicted outcome after HCT. Comparing patients transplanted in the periods 1991–1996 and 1997–2002, there was an improvement in 5-year survival rate: 74% versus 80%, respectively. In the period 1997–2002, actuarial survival was 91% for children (<16 years old) and 74% for adults. ATG was added to the conditioning regimen in 20% of patients and their overall survival was 81% compared with 73% among patients not receiving ATG [107].

Several other studies found a survival of more than 85% for patients conditioned with the regimen of CY (200 mg/kg) and ATG [61,86,108–110]. In contrast, reports of patients conditioned with CY and irradiation had survival rates ranging from 57 to 78% [109,113,114], although the follow-up on some of these reported studies was short. Pediatric patients (younger than 19 years) generally fared better than adult patients [29,73,85,86,111], with survival rates of 94–100%.

A striking difference in transplant outcome for AA between radiation- and non-radiation-based conditioning regimens was reported from a single center by Ades et al. [109]. From 1978 to 1992, 100 patients received A CY/TAI conditioning regimen and had an overall survival at 15 years of 58%. From 1995 onwards, 33 patients (26 under the age of 30 years) received CY + ATG conditioning with MTX + CSP GVHD prophylaxis and had a 94% overall survival.

Radiation-containing regimens were widely used in the late 1970s and 1980s because of their better immunosuppressive properties resulting in a decreased incidence of graft rejection. However, the use of radiation has been associated with risks of interstitial pneumonia, growth impairment, development of secondary solid tumors (see later discussion), and lower overall survival compared with CY and ATG. Radiation is no longer recommended as an initial preparative component for patients with HLA-matched sibling donors.

The steady improvement over the past four decades in overall survival after allogeneic HCT for SAA was recently threatened by the widespread use of G-PBHC and/or G-CSF primed bone marrow (G-BM) in place of unmodified bone marrow (BM). Two large registry studies have clearly demonstrated worse overall survival when either G-PBHC or G-BM was used instead of unmodified BM. A CIBMTR study compared outcomes in patients with SAA transplanted between 1997 and 2003, infused with BM (n = 547), G-BM (n = 78), or G-PBHC (n = 134) from HLA-identical siblings. There was no difference in the likelihood of achieving neutrophil recovery at 30 days after HCT or platelet recovery at 60 days after HCT among the three groups. However, there was a significantly increased risk of acute GVHD for G-PBHC recipients and an increased risk of developing chronic GVHD among G-BM and G-PBHC recipients compared with BM. The 3-year adjusted overall survival was 80, 72, and 76% for recipients of BM, G-BM, and G-PBHC, respectively. The difference in overall survival for G-BM recipients was significantly worse compared with unmodified BM [115]. An EBMT study with increased numbers of SAA patients showed a more striking difference in the overall survival in favor of unmodified BM. Among patients receiving HLA-identical sibling grafts between 1999 and 2009, 1163 received BM and 723 received G-PBHC and actuarial 10-year overall survival was 84 and 68%, respectively. Multivariate analysis identified the following negative predictors for overall survival: older age, longer interval between diagnosis and transplantation, no ATG in the conditioning regimen, a regimen other than CY 200 mg/kg, and G-PBHC as the stem-cell source. For patients age 20 years or less, the 10-year overall survival was 90 and 76% for BM and G-PBHC, respectively. For patients over 20 years of age, the 10-year overall survival was 74 and 64% for BM (n = 507) and G-PBHC (n = 489), respectively. When stratified for all negative predictors of survival, BM was consistently superior to G-PBHC in overall survival after HCT (Figure 46.3) [53]. In conclusion, there is no indication for the use of G-PBHC or G-BM as the stem-cell source for patients with SAA.

Transplantation for older patients

An analysis of 23 consecutive patients with SAA who were above the age of 40 years (range 40–68 years) and underwent BMT from HLA-identical siblings in Seattle with CY (200mg/kg) + ATG conditioning and MTX + CSP GVHD prophylaxis between July 1988 and October 2008 showed an overall survival of 65% with a median follow-up of 9.1 years. Five patients (22%) died from pre-existing infections prior to engraftment. Three patients died from infections at 3, 6, and 7 months after BMT related to acute or chronic GVHD. Six patients (26%) developed fluid overload, requiring specific medical treatment, either during the conditioning regimen or within the week after HCT; this complication was observed in the setting of concurrent systemic infection. Graft rejection was observed in 4%. The overall incidence of acute and chronic GVHD was 35 and 26%, respectively; grade IV GVHD was not observed. The median time to discontinuation of immune suppression was 6 months (range 6–92 months) [116]. These data support the use of BMT for patients with SAA well above the age of 40 years who have no significant medical comorbidities.

Registry data from CIBMTR identified 84 patients above 40 years of age with SAA who received HLA-identical sibling BMT following a wide variety of conditioning regimens (48% with standard CY + ATG) and reported 53% overall survival at 5 years. Independent risk factors for worse outcome included poor performance score and delay of greater than 3 months between diagnosis and transplant [117]. An analysis of older Korean patients transplanted with various conditioning regimens and cell sources, including 53% with standard CY + ATG and 74% with BM, reported that patients between age 40 and 50 years had a 5-year overall survival of 68% [118].

The outcome with a FLU (120 mg/m^2), CY (1200 mg/m^2), and rabbit ATG (15 mg/kg) conditioning regimen was reported in 30 patients with SAA over 30 years of age. Two-thirds received unmodified BM and one-third received G-PBHC from HLA-identical siblings. Most patients received CSP and MTX GVHD prophylaxis. There was one patient with graft failure and the incidence of acute and chronic GVHD was 10 and 13%, respectively. At a median follow-up of 4 years, the overall survival for the 21 patients above 40 years of age was 71% [34]. Finally, results from the FLU–CY–alemtuzumab regimen were reported in 12 SAA patients older than 50 years of age, with 71% overall survival at 2 years [32]. Although there may be an increased risk of subsequent graft rejection, the

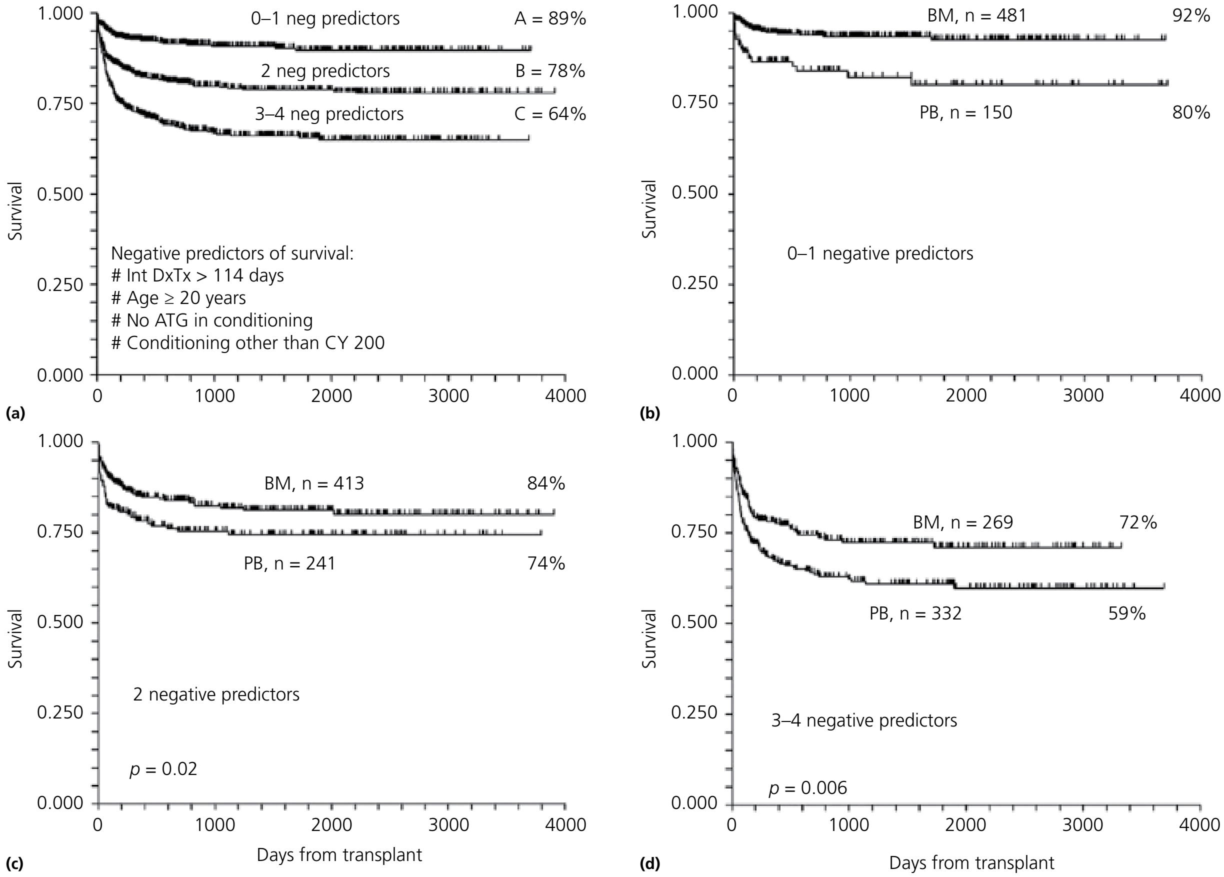

Figure 46.3 European Group for Blood and Marrow Transplantation (EBMT) registry data summarizing survival outcome in 1886 patients with acquired aplastic anemia who received a first transplant of HLA-identical sibling between 1999 and 2009 with either bone marrow (BM, $n = 1163$) or G-CSF-mobilized peripheral blood (PB, $n = 723$) as the source of stem cells. (a) Actuarial survival of all patients stratified by negative predictors of survival: interval diagnosis-transplant (Dx–Tx) ≥114 days, recipients' age ≥20 years, no antithymocyte globulin (ATG) in the conditioning, a conditioning regimen other than cyclophosphamide 200 mg/kg. Three groups were identified: low risk (survival 89%), intermediate risk (survival 78%), and high risk (survival 64%). (b) Actuarial survival for BM versus PB graft recipients in the low-risk group ($p = 0.0001$). (c) Actuarial survival for BM versus PB graft recipients in the intermediate-risk group ($p = 0.02$). (d) Actuarial survival for BM versus PB graft recipients in the high-risk group ($p = 0.006$). Source: Bacigalupo et al. 2012 [53]. reduced-intensity regimen of FLU–CY–alemtuzumab [32] or FLU–CY–rabbit ATG [34] with HLA-identical sibling bone marrow as the stem-cell source is an effective alternative treatment for older patients with SAA who are deemed unable to tolerate the standard higher dose CY 200 mg/kg + ATG regimen.

Influence of etiology of aplastic anemia on the outcome of marrow grafts

HCT can cure AA resulting from causes other than an idiopathic etiology, including patients with hepatitis-associated AA, Fanconi anemia, and dyskeratosis congenita. For hepatitis-associated AA, there was concern either that liver damage caused by hepatitis might lead to increased liver damage from CY or that the damaged liver might not be able to activate CY enzymatically. Neither of these concerns proved valid [119,120]. Marrow grafts were successful, even when CY was administered at times of highly abnormal liver function tests. Also, there were no long-term hepatic sequelae related to the HCT procedure in these patients. Survival was in excess of 80% [119].

Fanconi anemia is covered in detail in Chapter 76, but is often included in reports describing patients with SAA. Fanconi anemia is an autosomal recessive disease with progressive pancytopenia, chromosomal fragility, and hypersensitivity to DNA cross-linking agents that can progress to acute leukemia. Currently, the only successful treatment for marrow failure in patients with Fanconi anemia is HCT. Conditioning regimens used in the past to prepare Fanconi anemia patients for transplantation have been associated with considerable toxicity and transplant-related mortality [121,122]. In addition, irradiation and high-dose CY are associated with a very high risk of secondary malignancies [123]. It has been recognized that unlike patients with idiopathic AA, those with Fanconi anemia can be conditioned with lower doses of CY than conventionally used because of their unusual sensitivity to toxicity from alkylating agents [124]. Results from Curitiba in Brazil and Seattle showed that patients with Fanconi anemia can be transplanted successfully without incorporation of irradiation into the conditioning regimen with substantially lower doses of CY than used in the past [125]. Subsequently, further dosage reduction of CY to 15 mg/kg/day given for four consecutive days (total dose, 60 mg/kg) has been successful in achieving durable donor engraftment of HLA-identical sibling bone marrow accompanied with decreased toxicity and excellent long-term survival of 93% with follow-up to 7.9 years [126]. Similar results with CY 60 mg/kg combined with ATG have been reported [127]. Thus, the optimal total dosage of CY that will allow sustained engraftment with minimal toxicity appears to be 60 mg/kg. For patients who do not have an HLA-identical sibling donor, regimens have been developed that incorporate FLU and reduced-dose CY with low-dose TBI and either in vivo or ex vivo T-cell depletion.

Dyskeratosis congenita is a rare inherited syndrome of ectodermal dysplasia that is associated with AA in 50% of cases [128]. The initial trials using conventional conditioning regimens were associated with significant morbidity and mortality [129,130], particularly an increased incidence of late chronic pulmonary and vascular complications. Recent reports have shown successful outcomes in patients given a reduced-intensity conditioning regimen such as the Seattle nonmyeloablative regimen of FLU 90 mg/m^2 + 2 Gy TBI [131] or, alternatively, CY (60 mg/kg) + ATG [132].

HCT has also been used to treat SAA resulting from PNH and Diamond–Blackfan anemia [133–135]. PNH is discussed in greater detail in Chapter 47. PNH may be classified into three categories based on flow cytometry characteristics, reticulocyte count, serum LDH concentration, and bone marrow analysis, namely (1) classic PNH, with florid hemolysis and erythroid hyperplasia, (2) PNH in the setting of another bone marrow failure syndrome (SAA or MDS), and (3) subclinical PNH, with no clinical or biochemical evidence of intravascular hemolysis [136]. Patients with PNH in the setting of a bone marrow failure syndrome typically have less than 10% of nucleated cells deficient in glycosylphosphatidylinositol-anchored proteins (GPI-APs). Patients with bone marrow failure syndrome should have treatment focused on the underlying bone marrow failure with either allogeneic HCT or immunosuppressive therapy. PNH-AA syndrome has been reported to respond favorably to IST, hence allogeneic BMT is generally offered to younger patients and those with HLA-identical siblings or to those who have not responded to IST. All patients with clinically significant hemolysis (typically with >10% GPI-AP-deficient cells) should receive therapy with the complement inhibitor eculizumab to prevent ongoing intravascular hemolysis. Patients with classic PNH who fail to respond adequately to eculizumab therapy and who have persistent intravascular hemolysis and thrombotic events should consider proceeding to allogeneic HCT [136]. Although allogeneic HCT offers potentially curative treatment for PNH, fewer patients with classic PNH are undergoing HCT since the introduction of eculizumab. Long-term eculizumab treatment for patients with classic PNH has favorable survival [137]. A retrospective registry analysis compared the outcomes of 211 patients with PNH who received allogeneic HCT between 1978 and 2007 with those of 405 PNH patients who did not undergo HCT between 1950 and 2005. There did not appear to be a benefit for allogeneic HCT when patients were approximately matched based on the severity of thromboembolism and PNH disease. The 5-year overall survival for 118 patients with the PNH AA syndrome who underwent transplantation was 69%. Nearly half of these patients received high-dose CY + busulfan or CY + TBI based conditioning regimens [138]. The reduced-intensity conditioning regimen of FLU 90 mg/m^2 + 2 Gy TBI has been successful for patients with PNH [139]. It is likely that reduced intensity conditioning regimens will reduce transplant related mortality and may improve the overall survival after allogeneic HCT. Of 61 patients with Diamond–Blackfan anemia who were refractory to prednisone and other therapies reported to the CIBMTR, 41 received HLA-identical sibling transplantation with 76% survival at 4 years [140].

Late effects

Long-term survival

Long-term outcome among 212 patients transplanted for SAA was initially reported by the Seattle group in 1998 [101]. The survivors included children and adults (aged 1–42 years at the time of transplant); 93% were conditioned with CY ± ATG, and 89% received HCT from HLA-identical siblings. Chronic GVHD was the dominant risk factor for late complications. The 20-year survival among patients without chronic GVHD (n = 125) was 89% compared with 69% among those with chronic GVHD (n = 86) [101].

A subsequent study of late effects was reported among 137 pediatric patients with acquired SAA who were followed for nearly four decades after allogeneic HCT [27]. Transplantation regimens were primarily CY ± ATG (77%) and 18% had a TBI-based regimen. Donors were 88% family members, 12% unrelated, and 2% syngeneic. Bone marrow was the source of stem cells in 98.5% of transplants; cord blood was used in 1.5%. The incidence of chronic GVHD was 26%. With a median follow-up of 21.8 years, survival for acquired SAA at 30 years after HCT was 82%. The 30-year survival for patients without chronic GVHD was 83% and for those with chronic GVHD it was 62%. There was an increased incidence of thyroid function test abnormalities and secondary malignancies in recipients of TBI-based conditioning. CY recipients demonstrated normal growth, with basically normal development and pregnancies with mostly normal offspring. Quality of life studies in adult survivors of HCT indicated that patients were comparable to age-matched control subjects, except for difficulty in obtaining health and life insurance in 20% of HCT patients. The data indicate that the majority of long-term survivors after transplantation for AA during childhood can have a normal productive life [27].

Gonadal function and fertility (see Chapter 102)

Gonadal function in patients conditioned only with CY + ATG often returns to normal. Among 65 women between the ages of 13 and 25 years who received CY, all had evidence of recovery of ovarian function, whereas among women aged 26–38 years, 37% developed primary ovarian failure [26,141–144]. These data suggest that older age is a risk factor for ovarian failure. Testicular function returned to normal in most men aged 14–41 years who received CY + ATG only for conditioning [26]. Many successful pregnancies were reported after conditioning regimens containing CY + ATG only [101]. Among a cohort of 63 women who underwent HCT for SAA as children (median age at transplant 10 years), there were 73 evaluable pregnancies among women who received CY-based conditioning. The median age at time of the first pregnancy was 24 years and 82% of pregnancies resulted in live births. The infants born to these women were normal, except for one with congenital aortic stenosis. Among the 74 men with SAA who received the CY-preparative regimen, their partners had 59 evaluable pregnancies, 80% of which resulted in live births. The infants were normal except for two: one had hip dysplasia and the other cleft lip [27]. In contrast, pregnancy and fathering a child after conditioning with TBI were rare events. Among the 10 patients who received a 12 Gy TBI conditioning regimen for SAA, there were two women who also became pregnant, and both delivered normal infants. One of these women was 3 years of age at transplantation and the other 13 years [27]. There is insufficient information regarding fertility after FLU-based regimens, since these regimens are predominantly used for older patients.

Growth and development (see Chapter 102)

A study of hormonal function and growth after HCT found that children conditioned with CY only had normal height and normal thyroid and adrenal function, and no growth hormone deficiency. However, in children given TBI as part of the conditioning, although prepubertal growth in the first 3 years after transplant was normal, the final height was lower than the target height [145]. Therefore, TBI-containing regimens should be avoided in children if possible. Both children and adults treated with TBI-containing regimens were also more likely to develop thyroid dysfunction after transplantation [26], and these patients should be monitored with yearly thyroid function tests.

Secondary malignancies (see Chapter 104)

Since the first patients were transplanted successfully for AA over 40 years ago, data have been accumulated on the incidence and types of secondary malignancies resulting from HCT. Deeg et al. [123] described results in 700 patients with AA who had an estimated 14% incidence of secondary malignancies at 20 years. The cancer risk among transplanted patients was ninefold higher than that among the general population. Overall, 18 of 621 patients (excluding those with Fanconi anemia) developed secondary malignancies a median of 7.5 years post-transplant. Of the tumors, five were lymphoid malignancies seen a median of 3 months after transplant, and 13 were solid tumors occurring a median of 8.2 years after transplant. Nine of the solid tumors were squamous cell carcinomas of the head and neck and most of these patients were cured following surgical resection. All of the patients with lymphoid malignancies died, whereas 46% of those with solid tumors died. Significant risk factors for the development of secondary malignancies in this series included the use of azathioprine for chronic GVHD treatment, increased age, and use of irradiation in the conditioning regimen [123]. With regimens not containing irradiation there was a cumulative incidence of secondary cancers at 10 years of 1.4% [146] compared with a 22% (standard error ±11%) incidence at 8 years [147] with radiation-containing regimens. Other studies have also implicated irradiation-based conditioning regimens as risk factors for late malignancies [28,109], so these regimens should be avoided in HLA-identical HCT candidates. The incidence of secondary malignancy for 81 patients receiving CY + ATG conditioning is shown in Figure 46.1d.

Among the pediatric cohort of 137 patients with acquired AA treated in Seattle, 18 (13%) developed a secondary malignancy between 1 and 31 years after transplantation and this was fatal for four patients. The most common malignancy was squamous cell carcinoma, which occurred in seven patients and was the cause of death for one. Five of the seven with squamous cell carcinoma also had severe skin chronic GVHD. Three patients developed a thyroid malignancy, all of whom were successfully treated. Three patients developed breast cancer between 21 and 31 years after transplantation. This was the cause of death for one with invasive breast cancer, and the other two survivors had carcinoma in situ. Two patients developed hepatocarcinoma associated with hepatitis C (due to blood transfusion given prior to the availability of donor screening). This was the cause of death for one, and the other is alive after a liver transplantation. One patient developed MDS and underwent a second allogeneic HCT. One patient developed a melanoma 2 months after receiving the transplant, which was treated with resection. A final patient died of metastatic cervical cancer. The proportion of patients who developed a secondary malignancy was greater among the patients who had TBI in the conditioning regimen [27].

Chronic GVHD is also a risk factor for the development of solid tumors after transplant for AA, with an estimated 17–30% probability at 20 years for patients with both acute and chronic GVHD [59,101]. Carcinomas of the oropharyngeal mucosa developed in patients with a history of chronic GVHD. These findings were also confirmed in a larger study of 19,229 patients who had undergone transplantation between 1964 and 1992, which showed that chronic GVHD was associated with a significantly increased risk of squamous cell carcinoma of the buccal cavity and skin [148]. The severity of chronic GVHD and duration of IST for chronic GVHD appear to be risk factors for secondary malignancy. These findings emphasize the importance of avoiding infusion of buffy coat or G-CSF-mobilized PBHC to prevent chronic GVHD in patients with AA.

Newer reduced-intensity conditioning regimens (see Chapter 21)

Considerable interest has been generated recently with the development of reduced-intensity conditioning regimens, which can decrease transplant-related mortality and permit successful allogeneic HCT of older or medically infirm patients with hematologic malignancies or inborn errors of metabolism (see Chapter 21) [149–151]. The current standard CY (200 mg/kg) + ATG regimen for SAA is non-myeloablative, although it is a more intensive conditioning regimen than the newer, less intensive regimens with FLU and reduced-dose CY. Two fairly recently reduced-intensity regimens include FLU (30 mg/m^2/day × 4 days), CY (300 mg/m^2/day × 4 days), and rabbit ATG (Thymoglobulin, 3.75 mg/kg/day × 4 days) [34] and, alternatively, FLU (30 mg/m^2/day × 4 days), CY (300 mg/m^2/day × 4 days), and alemtuzumab (12 mg/day × 5 days, although lower doses may be sufficient) [32]. In the two clinical trials for SAA reported to date, a substantial number of patients received G-PBHC; however, bone marrow is the preferred source of stem cells. CSP and MTX was primarily used as post-grafting immunosuppression for the FLU–CY–rabbit ATG trial and CSP monotherapy was given after the FLU–CY–alemtuzumab regimen. However, it is unclear if the optimal alemtuzumab dose or the optimal post-grafting therapy has been identified for the FLU–CY–alemtuzumab regimen.

Whether or not an alternative conditioning regimen such as fludarabine or reduced-dose CY could be less toxic or better tolerated and yet as effective as CY 200 mg/kg + ATG for SAA patients remains to be determined. To date there is no evidence of improvement in the survival or definitive reduction in transplant-related mortality with the intensified FLU with reduced CY-based regimens. A report of six patients with SAA who received FLU 90 mg/m^2 and 2 Gy TBI, a G-PBHC graft, and the triple-drug GVHD prophylaxis regimen of CSP + MMF + MTX showed that all six patients survived with donor engraftment, although follow-up was brief [152]. These results suggest that alternatives to the standard CY (200 mg/kg) + ATG regimen are worth considering in the context of clinical trials for patients at high risk for medical complications from the CY 200 mg/kg and ATG regimen. Given the historical experience with high rates of graft rejection for transfusion-sensitized SAA patients, the potential benefit of a slight reduction in conditioning regimen toxicity must be very carefully balanced against the increased risk of complications associated with graft rejection or acute and chronic GVHD.

Grafts from alternative marrow donors

Transplantation of marrow obtained from unrelated or HLA-mismatched related donors has been less successful than grafts from HLA-identical siblings. There are probably two major reasons for this discrepancy:

1 there is an increased risk of transplant-related complications because of the greater genetic disparity between donors and recipients; and
2 most patients are not considered candidates for HCT from alternative donors until they have failed attempts at IST.

By the time these patients come to transplantation, they are often refractory to platelet transfusions, have received multiple antibiotics because of life-threatening infections, and are often severely infected at the time of transplantation. In order to improve patient survival, transplantation from alternative donors should be considered at earlier time points before patients become severely ill.

HLA-non-identical related donors (see Chapter 44)

Data from Seattle and the EBMT group indicate that patients transplanted for aplastic anemia with phenotypically HLA-matched related donors have better overall survival, ranging from 64 to 100%, than patients with HLA-mismatched related donors, whose survival is generally 50% or less [153,154]. For patients with phenotypically HLA-matched donors, irradiation proved not to be a necessary component of the conditioning regimen, and survival of CY-conditioned patients was similar to that of patients with HLA-identical sibling donors [153].

For patients with HLA-mismatched related donors, conditioning with CY with or without ATG did not provide sufficient immunosuppression to prevent graft rejection in most patients, and none of the patients achieved long-term survival. High rates of acute and chronic GVHD occurred among those few patients who did engraft. For subsequently transplanted patients with HLA-mismatched related donors, the use of CY combined with TBI decreased the incidence of graft failure and increased survival, but pre- and peri-transplant infections and post-transplant GVHD have remained major problems [153]. The optimal dose of TBI for these patients to prevent rejection with a minimal amount of regimen-related toxicity is not known.

Increasing HLA disparity adversely affects transplant outcome [153,154], consistent with findings in patients transplanted for leukemia [155]. A CIBMTR survey showed 49% projected survival for one HLA-locus mismatched HCT, similar to Seattle data that showed 50% survival for these patients [156]. The CIBMTR series reported 35% survival for two or more HLA-loci mismatched recipients, with other studies reporting similarly poor outcomes [153]. The Beijing transplant group reported on a cohort of 19 younger patients with SAA who received HLA-haploidentical family member donor G-BM combined with G-PBHC following conditioning with busulfan (BU 6.4 mg/kg intravenous), CY (200 mg/kg), and ATG (rabbit or pig). Post-grafting immunosuppression consisted of the triple regimen of MTX, CSP, and MMF. Two patients (11%) had late graft failure, and three patients did not achieve platelet engraftment. Acute GVHD developed in 42% and chronic GVHD in 56% of evaluable patients. The 2-year overall survival was 64%. Although these early survival results are better than expected, the increased risk of GVHD following this transplant regimen is of concern, and will limit the applicability of this approach for more patients with SAA [157].

Unrelated donors (see Chapter 45)

Most patients with AA who do not have suitably HLA-matched related donors receive IST as first-line therapy. They proceed to unrelated donor BMT only if they fail to respond to IST. Historically, rates of transplant-related morbidity and mortality have been high. In a National Marrow Donor Program (NMDP) retrospective analysis of 141 patients transplanted between 1988 and 1995, the overall survival at a median of 36 months after transplant was 36% [158]. Some 86% of these patients received a radiation-containing conditioning regimen, 74% received HLA-matched marrow, and 26% received marrow mismatched for at least one HLA-A, -B or -DR antigen; 32% received T-cell-depleted marrow, and all but 13% received a CSP-containing regimen to prevent GVHD. A total of 89% achieved sustained engraftment, and 52% of patients developed grade II–IV acute GVHD.

In a pilot study, five patients received unrelated donor transplants following CY and ATG conditioning as used for recipients of HLA-identical donor marrow. Three patients experienced graft failure and only one patient survived long term [159]. Other groups reported that high-dose irradiation regimens, although effective in achieving engraftment, resulted in an increased incidence of fatal organ toxicity without increasing the probability of survival.

In the past two decades, high-resolution HLA typing and identification of an optimized conditioning regimen have resulted in improved survival after unrelated donor HCT [160]. A collaborative multicenter prospective NMDP-sponsored study was undertaken to define the minimum effective dose of TBI sufficient to achieve engraftment for patients with AA transplanted with unrelated donor marrow [161]. The starting dose of TBI was 6 Gy (three fractions of 2 Gy) given after three doses of horse ATG 30 mg/kg/day, combined with four consecutive infusions of CY 50 mg/kg/day. The TBI dose was to be escalated in increments of 2 Gy if graft failure occurred in the absence of prohibitive toxicity, and de-escalated for toxicity in the absence of graft failure.

A total of 87 patients were enrolled between 1994 and 2004: 62 patients received HLA-A, -B, -C, -DR and -DQ-allele matched marrow transplants based on molecular typing and 25 patients received marrow from donors who differed by one or two alleles or one HLA antigen. The ages of the patients ranged from 1.3 to 53.5 years with a median of 18.6 years. The time intervals from diagnosis to transplantation were 2.8–328 months with a median of 14.6 months. All patients had received multiple transfusions and a median of three courses of IST. All 20 patients treated with 6 or 4 Gy TBI, CY, ATG, and HLA-matched marrow engrafted, and survival was 50%. Of the 35 patients receiving 2 Gy TBI, CY, ATG, and HLA-matched marrow, one rejected and 23 (66%) were alive. Grade 3 or greater pulmonary toxicity occurred in eight of 30 patients conditioned with 6 or 4 Gy TBI and in one of 35 patients conditioned with 2 Gy TBI. The incidence of acute GVHD was 69%, with eight deaths attributable to acute or chronic GVHD and infection. Chronic GVHD requiring therapy developed in 52% of patients. Nine patients did not tolerate ATG and instead received CY 120 mg/kg and fractionated 12 Gy TBI; five of the nine survived [161].

Age was an important risk factor for survival. Patients who were under the age of 20 years at the time of HLA-matched unrelated BMT conditioned with 2 Gy TBI + CY + ATG had a 5-year survival of 78% compared with 50% for patients older than 20 years. Recipients of HLA-non-identical unrelated donor grafts had an overall survival of 40% [161]. CIBMTR data for unrelated donor HCT showed that among 181 patients transplanted with low- or intermediate-resolution HLA-matched unrelated donor marrow between 1988 and 1998, the 5-year survival probability was 39% [156]. As multiple suboptimal preparative regimens were used, and high-resolution HLA typing was not applied, the results are inferior to those with the new regimen identified by Deeg et al. [161] for unrelated HCT. Most unrelated transplants were performed late in the course of disease after failure to respond to one or more courses of immunosuppression. Furthermore, it is now accepted that the widespread adoption of improved molecular techniques for high-resolution HLA typing will result in better outcomes for recipients of HLA-matched unrelated donor HCT [162].

Table 46.2 summarizes the hematopoietic cell transplant results for patients who received marrow grafts from HLA-matched unrelated donors. In these studies, patients who were younger than 20 years had better survival. As with transplants using HLA-mismatched related donors, non-radiation-containing conditioning regimens provided insufficient immunosuppression to prevent rejection among patients receiving unrelated marrow grafts [159].

In summary, the NMDP-sponsored study reported by Deeg et al. [161] showed improved outcome of patients and identified a conditioning regimen of 2 Gy TBI, CY, and ATG that achieved reliable engraftment with significantly decreased organ toxicity. These results, combined with the recent advances in molecular HLA typing, now strongly suggest that patients who have unrelated donors fully HLA matched for both class I and II, including HLA-C, by high-resolution DNA-based typing may have superior long-term outcome with HCT over IST. If a high-resolution 10 of 10 HLA-allele matched donor is identified, then unrelated donor HCT should be considered early in the course of treatment of patients with SAA, even as first-line therapy, particularly for patients 20 years of age or younger. Because of the time interval involved in the donor search, unrelated donor HCT might not be feasible as first-line therapy for acquired SAA. However, patients could proceed to unrelated donor HCT within 4 months if response to IST was unsatisfactory. As with the HLA-identical sibling setting, transfusion with leukodepleted irradiated blood products prior to transplantation is critical to decrease the risk of graft rejection. Although confirmatory data are lacking, younger patients (less than 35 years of age) with 1-HLA-allele mismatched donors could also proceed to BMT if treatment with one or possibly two optimal IST regimens had failed [161].

Recently, a Blood and Marrow Transplant Clinical Trials Network (BMT CTN) multicenter phase I/II study was conducted to identify the optimal dose of CY when used in a FLU (120 mg/m^2)–CY–ATG–2 Gy TBI conditioning regimen. There were four cohorts of CY: 150, 100, 50, and 0 mg/kg. All patients received either 3 mg/kg/day × 3 doses (9 mg/kg) of rabbit ATG or 30 mg/kg/day × 3 doses (90 mg/kg) of horse ATG. Bone marrow from an HLA-matched unrelated donor was the source of hematopoietic stem cells (a single HLA-locus mismatch was acceptable). CY 150 mg/kg was associated with a high incidence of pulmonary toxicity and death (seven

[a] Includes nine patients who did not tolerate ATG, and received CY (120 mg/kg) + 12 Gy TBI.

[b] 5-year survival among 23 patients aged ≤20 years conditioned with 2 Gy TBI and disease duration less than 1 year was 85%.

[c] BMT CTN trial is a dose-finding study comparing conditioning regimen CY 150, 100, 50 or 0 mg/kg + FLU 120 mg/m^2 + ATG (rabbit or horse) + 2 Gy TBI. Study is continuing accrual with randomization of patients to CY 50 vs. 100 mg/kg dose.

of 14 patients died from organ failure or acute respiratory distress syndrome) and CY 0 mg/kg was associated with a high incidence of secondary graft failure (three of three patients). The study will continue to accrue patients in two arms of CY dose, 50 vs. 100 mg/kg [163]. It is not yet clear if the outcome from the CY 50 or 100 mg/kg combined with FLU 120 mg/m^2, ATG, and 2 Gy TBI is superior to the standard CY(200 mg/kg)–ATG–2 Gy TBI regimen. As has been suggested by some of the HLA-identical sibling studies, it may be that the combined FLU-reduced dose CY regimen is better suited for older patients with SAA receiving unrelated donor BMT.

United Kingdom BMT centers reported on a cohort of consecutive children (age 1–17 years) with SAA diagnosed between 2000 and 2010, who initially underwent treatment with IST consisting of rabbit ATG plus CSP, followed with unrelated donor HCT when IST failed to control SAA. Among 43 evaluable children, the efficacy of first-line rabbit ATG + CSP IST was low, with a 6-month cumulative response rate of 32.5%. Next, 44 children received unrelated donor HCT, 40 of whom had failed prior rabbit ATG and CSP. The transplant conditioning regimen varied, but consisted primarily of FLU (150 mg/m^2), CY (either 120 or 200 mg/kg), and alemtuzumab (1 mg/kg total dose). Most patients received unmanipulated BM from HLA-matched unrelated donors and post-transplant immunosuppression consisted of CSP or a combination of CSP with MMF or MTX. The median follow-up was 2.9 years, there was no graft rejection, and the cumulative incidence of acute and chronic GVHD was 38 and 11%, respectively. The 5-year estimated overall survival was 95% [164]. This study demonstrated the efficacy of a rather immunoablative FLU–CY–alemtuzumab conditioning regimen without the need for TBI in children with SAA undergoing unrelated donor HCT.

Similarly to findings from HLA-identical sibling HCT for SAA, bone marrow is the preferred source of stem cells from unrelated donors. A CIBMTR study compared outcomes for patients with SAA who received an HLA-allele matched unrelated donor (matched at HLA-A, -B, -C, and -DRB1) transplant between 2000 and 2008 after a variety of standard conditioning regimens: 225 received unmanipulated BM and 71 patients received G-PBHC. Hematopoietic recovery was similar after G-PBHC and BM transplantation. Grade II–IV acute GVHD was increased after transplantation of G-PBHC compared with BM (48% vs. 31%, Figure 46.4a). Chronic GVHD was not different after adjusting for age at transplantation (Figure 46.4b). Mortality risks, independent of age, were higher after G-PBHC compared with BM transplantation (HR 1.62, $p = 0.04$). The 3-year overall survival was 61 and 76% after G-PBHC and BM transplantation, respectively (Figure 46.4c) [165]. Although this was not a randomized study, the conclusions are strongly in favor of using only unmodified BM and completely avoiding G-PBHC from unrelated donors as the stem-cell source for transplantation of patients with SAA.

Although a fully HLA-allele matched donor is preferable, a recent analysis by the Japan Marrow Donor Program (JMDP) suggests that certain HLA-allele mismatches are acceptable for younger patients with SAA [166]. Reviewing the 380 consecutive unrelated donor bone marrow transplants performed between 1993 and 2005 in Japan, a total of 301 patient and donor pairs were available for HLA-A, -B, -C, -DRB1 and -DQB1 DNA sequence analysis. Based on DNA sequencing for HLA typing completed after the transplant, patients were categorized into five groups: Group 1, complete match at HLA-A, -B, -C, -DRB1 and -DQB1 (33% of patients); Group 2, single allele mismatch at HLA-A or -B (7%); Group 3, single allele mismatch at HLA-C, -DRB1 or -DQB1 (16%); Group 4, multiple alleles mismatched restricted to HLA-C, -DRB1, and -DQB1 (23%); Group 5, all other HLA allele mismatches (21%). The median age at BMT was 17 years, the median disease duration prior to BMT was 43 months, and all patients had failed conventional IST. Various conditioning regimens were used, including predominantly TBI- or LFR-based regimens combined with either CY ± ATG, or with FLU + CY ± ATG. The incidence of neutrophil engraftment at day 42 after BMT was 90% for the entire cohort, and was highest in Group 1 and lowest in Group 5 at 93 and 84%, respectively. The incidence of grade II–IV acute GVHD was lowest in Group 1 and highest in Group 5 at 15 and 38%, respectively. The cumulative incidence of chronic GVHD was 25% in the entire cohort and was not significantly different between the five groups. The 5-year overall survival was 66% for the entire cohort and greatest in Group 1 and lowest in Group 5 at 75 and 47%, respectively. Multivariate analysis indicated that only HLA disparity of Group 5 (multiple HLA-allele mismatches not only restricted to HLA-C, -DRB1, and -DQB1) was a significant risk factor for poor survival (relative risk 1.96, $p = 0.02$). HLA-DPB1 mismatching was not associated with any clinical outcome. The results suggest that the use of an HLA 10 of 10 allele matched donor is preferable. However, if such a donor is not available, any single- or multiple-allele (HLA-C,-DRB1,-DQB1)-mismatched donor is acceptable as an unrelated donor for patients with SAA [166].

Umbilical cord blood (see Chapter 39)

A potential advantage of using umbilical cord blood (UCB) as a source of HSC for unrelated donor transplantation in SAA is that UCB is already stored and promptly available for transplantation and HLA mismatching is better tolerated and therefore may be considered when a sufficiently HLA-matched unrelated donor marrow is not available. Published data for acquired AA UCB transplantation are limited. Furthermore, the low cell dose obtained from a UCB donation poses particular problems in SAA, where an increased HSC dose is important to increase the likelihood of sustained engraftment. Initial reports of cord blood transplantation for SAA were very discouraging because of a very high incidence of graft rejection and transplant-related death [167]. The recent introduction of two-unit UCB transplants as a means of increasing the hematopoietic progenitor cell dose for adult recipients has been successful in achieving a high engraftment rate in patients with high-risk MDS/leukemia. Typically, for each two-unit UCB transplant recipient, only one of the two infused units engrafts long term [168]. However, two-unit UCB transplantation is associated with an increased risk of acute GVHD. Despite the broader introduction of two-unit UCB transplantation, the overall low cell dose of hematopoietic progenitor cells in cryopreserved cord blood units continues to limit the more widespread application of this approach for adults with SAA. Several recent reports support the role of UCB transplant for SAA.

In the setting of UCB transplantation, conditioning regimens containing ATG were associated with worse overall survival, apparently due to delayed immune reconstitution and increased infectious complications. The Japan Cord Blood Bank Network (JCBBN) reported on the initial experience with 31 SAA patients with a median age 28 years who received single-unit UCB transplantation following diverse conditioning regimens. The overall cumulative incidence of neutrophil recovery was 55%, and the incidence of acute and chronic GVHD was 17 and 20%, respectively. Overall survival was 41% at 2 years. One conditioning regimen consisting of low-dose TBI (2–5 Gy), FLU, and CY given to five patients had an overall survival of 80% [169].

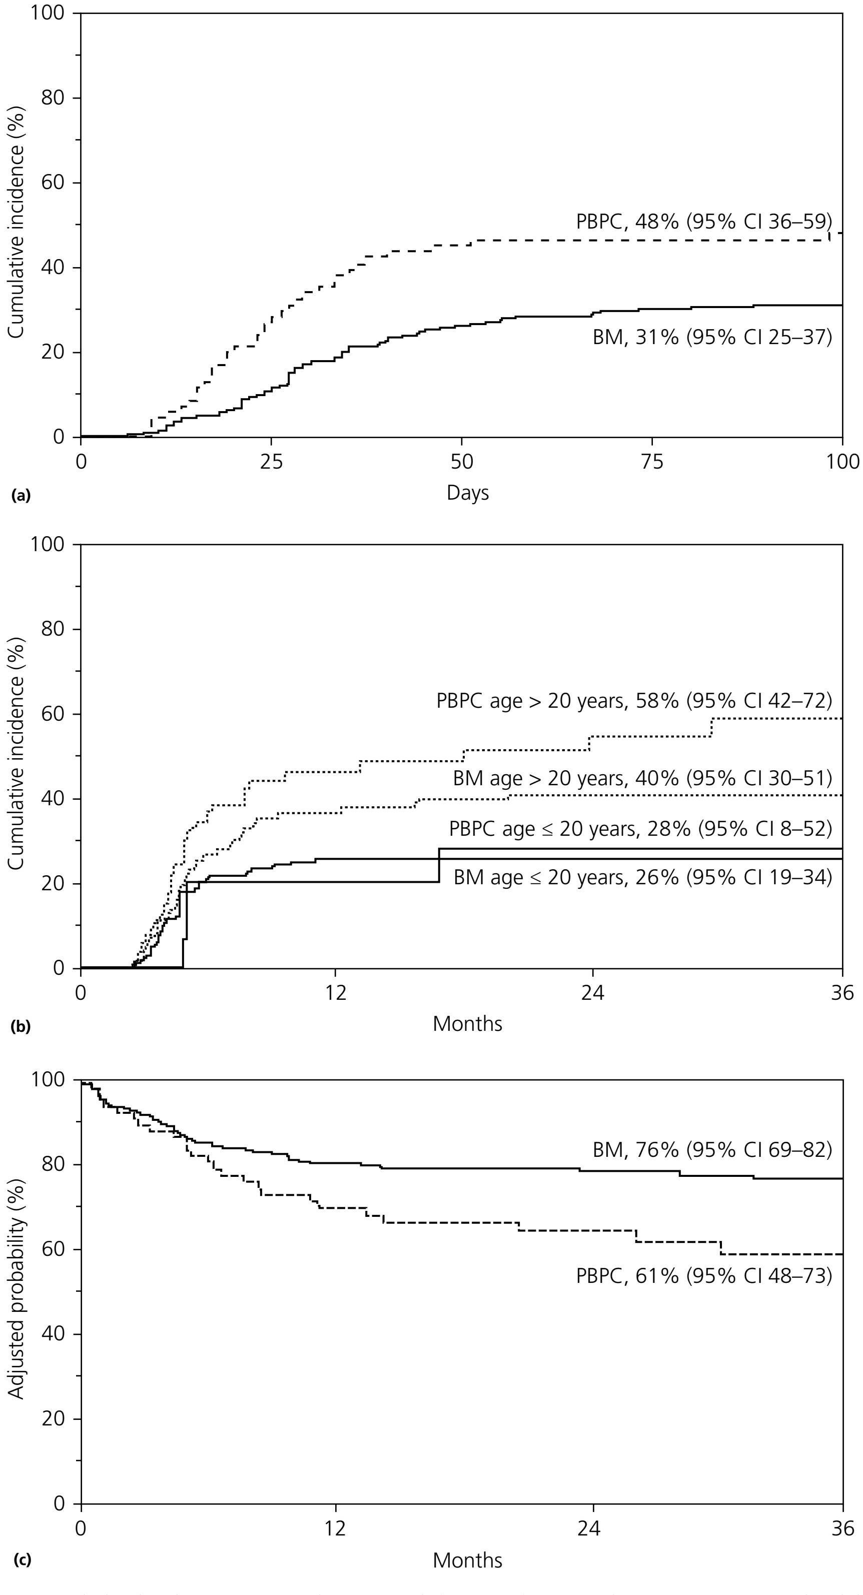

Figure 46.4 Center for International Blood and Marrow Transplant Research (CIBMTR) registry data summarizing unrelated donor hematopoietic cell transplant outcome for patients with severe aplastic anemia. Comparison of patients receiving either bone marrow (BM, *n* = 225) or peripheral blood progenitor cells (PBPC, *n* = 71) from unrelated donors matched at human leukocyte antigen-A, -B, -C, -DRB1. (a) Incidence of grade II–IV acute graft-versus host disease (GVHD). (b) 3-year cumulative incidence of chronic GVHD after PBPC and BM transplantation in patients aged <20 and ≥20 years at transplantation. (c) 3-year probability of overall survival after PBPC and BM transplantation (*p* = 0.04). Source: Eapen et al. 2011 [165]. Reproduced with permission of the American Society of Hematology.

A follow-up Japanese study of 12 SAA patients with a median age of 49 years used a reduced-intensity conditioning regimen consisting of 4 Gy TBI, FLU (125 mg/m^2), and melphalan (MEL) (80 mg/m^2) and single-unit UCB transplantation. The median infused total nucleated cell (TNC) dose was 2.5×10^7/kg. Most patients received tacrolimus/MMF post-grafting immunosuppression; 42% developed grade II acute GVHD. Ten of 12 patients had sustained engraftment; in addition, two patients died of idiopathic pneumonia syndrome. At a median of 36 months after UCB transplantation, 10 of the 12 patients were alive [170].

The EBMT group reported on 71 patients with SAA, including nine with PNH, transplanted with a variety of conditioning regimens and UCB between 1996 and 2009 with a median age 13 years. Either single- or double-unit UCB infusion was given to 80 and 20%, respectively, and 68% received a reduced-intensity conditioning regimen. The cumulative incidence of neutrophil recovery was 51% at day 60, with significantly improved engraftment in recipients of units with prefreezing TNC dose $>3.9 \times 10^7$/kg. The incidence of platelet engraftment was 37% at day 180, and the incidence of acute and chronic GVHD was 20 and 18%, respectively. With a median follow-up of 35 months, the 3-year overall survival was 38%. Recipients of UCB units with a prefreezing TNC dose $>3.9 \times 10^7$/kg had a 3-year overall survival of 45% compared with 18% for recipients of $<3.9 \times 10^7$ TNCs/kg. These results emphasize the importance of cell dose for both engraftment and overall survival in patients with SAA undergoing UCB transplantation [171]. In summary, although the outcome of UCB transplantation for SAA is not as favorable as with HLA-matched unrelated donor BMT, for patients who lack a suitably HLA-matched donor, UCB transplantation offers effective salvage therapy for those with refractory SAA who have failed to respond to one or two courses of IST, provided that the infused UCB cell dose is adequate (ideally $>4 \times 10^7$ TNCs/kg). Additional clinical trials are needed to confirm the efficacy of the TBI–FLU–MEL regimen [170] or other reduced-intensity regimens for UCB transplantation.

Non-transplant approaches

The value of immunosuppressive agents for the treatment of AA was first described by Mathé et al. in Paris in 1970 [172]. They observed recovery of autologous hematopoiesis in patients conditioned with antilymphocyte globulin (ALG) administered in preparation for transplants of marrow from HLA-mismatched donors. Later prospective studies showed that the mismatched marrow graft did not contribute to the responsiveness, and subsequently ALG or ATG was used alone to treat patients with AA. More recently, CSP with or without corticosteroids was added to ATG or ALG [173].

For patients who are not candidates for first-line BMT, the combination of ATG and CSP is the currently recommended immunosuppressive regimen for AA. The response rate to IST (as defined by transfusion independence) for patients with severe AA was 60–70% at 3–4 months [174,175]. Long-term follow-up from a German prospective multicenter randomized trial comparing ATG alone with ATG and CSP reported an overall survival of 54 and 58%, respectively, at 11 years. The addition of CSP significantly improved early response to ATG treatment, but because of the efficacy of salvage CSP treatment, there was no overall survival benefit. Failure-free survival, defined as survival in the absence of relapse, no response, PNH, MDS, acute myeloid leukemia (AML), or solid tumors, favored the combined ATG and CSP regimen (39% vs. 24%). Normalization of blood counts occurred in one-third of patients. Risk of relapse was 38%. Remissions were CSP dependent in 26% of patients treated with CSP, necessitating long-term maintenance of the drug. Clonal or malignant diseases developed in 25% of the patients. The actuarial probability of developing hemolytic PNH, MDS/AML, or a solid tumor after IST was 10, 8, and 11%, respectively, at 11 years [175]. The National Institutes of Health (NIH) Hematology Branch retrospectively analyzed risk factors predicting hematologic response to IST. Younger age, absolute reticulocyte count (ARC) $>25 \times 10^9$/L, and absolute lymphocyte count (ALC) $>1 \times 10^9$/L were associated with hematologic response to ATG and CSP at 6 months. Patients with higher ARC and ALC had 83% response versus 41% for patients with lower ARC and ALC [176].

In a randomized study conducted at the NIH, rabbit ATG was demonstrated to be inferior to horse ATG as first-line IST treatment for SAA. A total of 120 consecutive patients with SAA who were not considered candidates for BMT as first-line treatment, 2–77 years of age, were randomly assigned to horse ATG or rabbit ATG (60 in each group). Horse ATG (ATGAM, Pfizer) was administered at a dose of 40 mg/kg/day × 4 days and rabbit ATG (Thymoglobulin, Genzyme) at a dose of 3.5 mg/kg/day × 5 days. CSP was given twice daily from day 1 and continued for at least 6 months in both ATG groups; the dose was adjusted to maintain blood trough levels of 200–400 ng/mL. The two groups were equally matched in patient characteristics and the median follow-up was 28 months. The hematologic response rate at 6 months was 68% with horse ATG and 37% with rabbit ATG ($p < 0.001$). The majority of patients had a response by 3 months, and only four patients in the horse ATG group and two in the rabbit ATG group had a response between 3 and 6 months. The incidence of clonal evolution in all patients at 3 years was 21% in the horse ATG group and 14% in the rabbit ATG group. The overall survival at 3 years was 96% in the horse ATG group and 76% in the rabbit ATG group when data were censored at the time of BMT, and 94 and 70% in the two groups, respectively, when the data were not censored at the time of BMT (Figure 46.5) [177]. Lymphopenia was more protracted in the rabbit ATG recipients, with significantly lower CD4 T cells for a prolonged duration. The results suggest that depletion of CD8 T cells is linked to the

Rabbit ATG	60	41	22	6

Figure 46.5 Randomized trial conducted at the National Institutes of Health, Bethesda, MD, comparing front-line non-transplant therapy with two antithymocyte globulin (ATG) formulations, horse versus rabbit, combined with cyclosporine (CSP). The 3-year overall survival rate was 94% in the horse ATG group ($n = 60$) versus 70% in the rabbit ATG group ($n = 60$) ($p= 0.008$); the data were not censored at the time of proceeding to hematopoietic cell transplantation. Source: Scheinberg et al. 2011 [177]. Reproduced with permission of the American Society of Hematology.

success of treatment and that the profound loss of CD4 T cells may be detrimental. Although horse ATG is not available in many countries outside the United States, this agent combined with CSP appears to be the most effective first-line IST for SAA [177]. A follow-up report from the EBMT SAA working party also confirmed the finding that rabbit ATG + CSP was significantly less effective than horse ATG + CSP for initial IST for patients with transfusion-dependent, non-severe AA [178].

The question of whether there is a benefit in the addition of G-CSF to ATG and CSP for first-line IST was definitively addressed in a recently completed randomized EBMT study of 192 patients with SAA [179]. For patients randomized to treatment with G-CSF, the drug was started on day 8 of treatment and continued daily until remission or day 240. No difference in overall survival or event-free survival was observed at 6 years between the two groups. Among patients with very severe AA treated with G-CSF versus no G-CSF, there was a reduced rate of early infections, 32% versus 52%, respectively, and duration of hospitalization. Multivariate analysis showed that (1) age at time of enrollment in the study and (2) severity of AA were significantly associated with overall survival.

Furthermore, the use of high-dose G-CSF for prolonged duration with IST has been reported to be a risk factor for the development of MDS/AML with monosomy 7, particularly in children [180]. A European survey included 840 patients who received a first-line IST with (43%) or without (57%) G-CSF. The incidences of MDS/AML in patients who did or did not receive G-CSF were 10.9 and 5.8%, respectively. A significantly higher HR (1.9) of MDS/AML was associated with the use of G-CSF [181].

Alternative treatment to ATG and CSP has also been explored. In a study that extended over 9 years, 10 patients were treated with a high dose of CY 180 mg/kg without marrow rescue, and seven patients responded with increases in peripheral blood counts so that they no longer met the criteria for SAA. Six patients were alive and without relapse or clonal disorders with a follow-up of 21–31 years [182,183]. A more recent follow-up study of 44 patients with treatment-naïve SAA and 23 with refractory SAA received 50 mg/kg/day CY for four consecutive days without CSP but with G-CSF support. The estimated probability of 10-year survival was 88%, the hematologic response rate was 71%, and the event-free survival was 58% for treatment-naïve patients. Patients with refractory SAA fared less well, with 10-year survival, response, and event-free survival of 62, 48 and 27%, respectively. Among responders to CY treatment, the median time to recovery of neutrophil counts (ANC $>0.5 \times 10^9$/L) was 60 days and the median time to independence from transfusion support was 6 months. The primary cause of death was invasive fungal infections, and most infections began within the first 2 months of treatment. For the treatment-naïve and -refractory SAA patients, the incidence of severe invasive fungal infections was 21 and 49%, respectively [183]. However, a randomized trial conducted at the NIH that compared high-dose CY with ATG (both treatment groups included CSP) was terminated early because of excessive infectious mortality in the CY group [184]. In the NIH study, CY induced prolonged pancytopenia, which contributed to the increased risk of infectious deaths. It was concluded that high-dose CY without allogeneic HCT was a dangerous choice for treatment of AA. In a subsequent report of late complications, relapse of disease and clonal evolution of cytogenetic abnormalities occurred in both the ATG and the CY treatment groups [185]. Given these results, high-dose CY alone without subsequent HCT is not recommended as an alternative IST regimen for the treatment of SAA.

The addition of drugs to the standard ATG and CSP regimen has been routinely reported in the literature as novel therapy for SAA. Multiple regimens have been explored as alternatives to ATG and CSP IST without evidence of benefit in response rates or survival [186]. Alemtuzumab monotherapy has poor efficacy for either treatment-naïve or -refractory SAA, but it may have activity when used as second-line IST for treatment of relapsed SAA [187]. Eltrombopag (an oral thrombopoietin mimetic, daily dose up to 150 mg) was studied in 25 patients with SAA that was refractory to ATG and CSP IST. Eleven patients (44%) had a hematologic response in at least one lineage at 12 weeks and only 28% had a prolonged response with platelet transfusion independence and improvement of either red blood cells or neutrophils [188]. These agents have low efficacy but may be helpful as salvage therapy in patients who are not able to proceed to allogeneic HCT.

Comparison of immunosuppressive therapy and hematopoietic cell transplantation

Several reports have compared the effectiveness of conventional IST and HCT. There have been no randomized trials comparing IST with HCT. Recent and earlier studies have consistently shown that there was a clear survival benefit for patients who underwent HLA-matched HCT [9,107,111,116,189–191].

An earlier large Seattle trial compared the outcome of 168 patients treated with BMT and 227 patients receiving IST between 1978 and 1991. In this study, many of the patients treated with BMT already had failed initial IST. Overall survival in this study at 15 years was 69% for the BMT patients and 38% for patients receiving IST ($p < 0.001$) [189]. The higher overall survival with BMT compared with IST was seen in all groups of patients under 40 years of age. In a long-term study of 100 consecutive children under the age of 17 years with SAA, the Nagoya transplant team confirmed that HCT was superior to IST [190].

Similarly to the results from Seattle, an updated retrospective survival analysis was completed based on the initial treatment offered to 2479 consecutive patients with SAA reported to the EBMT registry from 1991 to 2002 [107]. A total of 1567 patients received BMT and 912 patients received IST. The actuarial 10-year survival was 73 and 68% for patients treated with BMT and IST, respectively ($p = 0.002$). Comparing the two periods 1991–1996 and 1997–2002, BMT outcome for all patients improved significantly with time, with overall survival of 69 and 77%, respectively, $p = 0.001$. Survival improved over time for both recipients of matched sibling donor (74 and 80%, $p = 0.003$) and for alternative donor recipients (38 and 65%, $p = 0.0001$) transplants. After BMT, survival in children was 79% compared with 68% in adults ($p < 0.0001$). In multivariate analysis, favorable predictors of BMT outcome were younger age, transplant after 1996, an HLA-identical sibling donor, a brief time interval from diagnosis to transplantation, and no irradiation in the conditioning regimen ($p < 0.001$). In contrast to the outcome with BMT, there was no significant improvement over time for patients receiving IST (69% survival for patients treated from 1991 to 1996 and 73% for patients treated from 1997 to 2002, $p = 0.29$). Survival after IST was significantly better in children than adults (81 and 70%, $p = 0.001$). Overall survival after IST for patients with severe AA was better in children (83%) than adults (62%) ($p = 0.0002$) [107].

One important difference between IST and HCT is that immunosuppression alone may not correct the underlying marrow abnormality. Up to 30% of IST patients develop disease relapse, that is, they have a return of their marrow aplasia, and a substantial proportion may develop clonal abnormalities including MDS and AML [31,174,181,192,193]. In a report of 50 children treated with a combination of G-CSF and CSP, 22% developed MDS or AML [194]. In another study of immunosuppression with ATG and CSP, survival was 72% at 2 years, but 10% of patients had developed PNH [195]. One study compared the incidence of secondary malignancies among patients with HCT versus IST. Forty-two malignancies were noted in 860 patients receiving IST whereas nine were reported in 748 patients who received HCTs. Overall, the 10-year cumulative incidence of cancer was 18.8% after IST and 3.1% after HCT. In this study, MDS and acute leukemia were seen exclusively in patients treated with IST whereas the incidences of solid tumors after IST versus HCT were similar [193]. The relatively high incidence of malignancies after IST was in agreement with earlier work by Tichelli et al. [196], who reported an incidence of PNH, MDS and acute leukemia as high as 57% at 8 years after treatment. Thus, long-term survival curves after IST have as yet not become stable, in contrast to those after HCT.

For some patients, the decision to proceed with BMT versus IST as first-line therapy depends on failure-free survival and quality of life issue analyses. One retrospective study compared quality of life outcomes between 52 transplanted patients and 155 patients receiving IST during 1976–1999. Overall and event-free survival were similar between the two groups. However, quality-adjusted time without symptoms and toxicity analysis showed that, compared with BMT, IST-treated patients had longer periods of time with (a) symptoms from drug toxicity, (b) transfusion dependency, (c) partial remission, and (d) secondary clonal disorders. Transplanted patients spent more time in complete remission without drugs and had longer periods free from symptoms [191].

In most registry studies of IST versus HCT, patients received IST because they lacked an HLA-identical family member donor and were generally not offered unrelated donor transplants as salvage if they failed IST, because at the time of these studies very little had been published about successful unrelated donor HCT for AA. With the recent increased success of unrelated donor HCT, the salvage rate for patients first given a trial of IST may be considerably greater than seen in the past. This result could change the relative benefits of early transplantation from an unrelated donor versus an initial trial of IST.

In summary, over the past four decades, overall survival has improved among patients with AA undergoing allogeneic HCT. There has also been an improvement in survival among patients treated with IST, although the improvement was not as significant as with allogeneic HCT. Based on a review of results to date, for patients up to age 65 years with an HLA-identical sibling, HCT with CY + ATG conditioning and MTX + CSP GVHD prophylaxis provides superior overall survival and should be recommended as first-line therapy over IST. Patients under 20 years of age with a 10/10 HLA-allele matched unrelated donor should proceed directly to HCT with the CY + ATG + 2 Gy TBI conditioning regimen followed by MTX + CSP GVHD prophylaxis. Older patients or patients who do not have an HLA-allele matched unrelated donor should receive first-line IST with CSP + ATG. If there is failure of IST after 3 months, patients should proceed to an unrelated donor HCT.

Conclusion

There are at least two reasons for the improved survival of patients with AA who were treated with HLA-identical HCT. One is the decreased incidence of graft rejection. The decline in rejection has resulted from the more judicious use of transfusions before HCT, the removal of sensitizing white blood cells from transfusion products, the irradiation of blood products before transfusion, and improvements in the immunosuppressive qualities of the conditioning programs used to prepare patients for transplantation. Irradiation-based programs have been effective but at the price of more transplant-related complications, and the CY–ATG combination is just as successful in preventing rejection with better long-term survival. With regard to transfusions before HCT, in vitro irradiation of all blood products may further reduce the risk of sensitization to minor histocompatibility antigens in the future [40,42]. The second reason for improved survival has been a decrease in the incidence and severity of acute GVHD through the introduction of better GVHD prevention regimens, such as combined MTX–CSP. The incidence of chronic GVHD may be decreasing, but mortality from it has not changed much despite prompt therapy. Therefore, better ways of preventing chronic GVHD are necessary, such as targeting the total corrected donor marrow cell dose to 2.0–2.5 × 10^8 cells/kg [59]. As more patients become long-term survivors, the problem of long-term sequelae from the initial conditioning programs and from certain post-grafting immunosuppressive agents such as azathioprine must be considered, in particular secondary cancer. In future studies, perhaps less toxic conditioning programs can be developed, particularly for older patients with medical comorbidities. Radiation-based regimens should not be used in HLA-identical recipients because of the greater likelihood of inducing secondary cancer, the deleterious effect on fertility, and the potential detrimental effects on growth and development for pediatric patients.

For patients without HLA-matched sibling donors, transplantation from HLA-mismatched related donors or unrelated donors should be considered. Prompt initiation of an unrelated donor search is needed after diagnosis of SAA in case there is failure to respond to IST within 3 months. Radiation appears to be an essential part of the currently used conditioning regimen for patients with alternative donors to prevent rejection. Recent results with unrelated donor marrow transplantation indicate that 2 Gy TBI, CY (± FLU) and ATG conditioning and combined MTX and CSP post-grafting immunosuppression were sufficient to prevent graft rejection and avoid TBI-induced organ toxicity [161,163]. The use of molecular-based methods for identifying optimally HLA-allele matched unrelated donors is critical to improve survival after transplant further. Cord blood transplantation is a salvage treatment option for patients who have failed to respond to IST and do not have a suitably HLA-matched unrelated donor, but only if there is a sufficient cell dose available (TNC >4 × 10^7/kg) [171].

CHAPTER 47

Hematopoietic Cell Transplantation for Paroxysmal Nocturnal Hemoglobinuria

Ryotaro Nakamura
City of Hope Medical Center, Duarte, CA, USA

Introduction

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal hematopoietic stem-cell disease disorder that manifests with intermittent hemolysis, thrombotic events, or pancytopenia [1–3]. It is a rare disorder that can occur at any age and across all human populations, with an estimated prevalence of 1–10 per million population [4,5]. Low-frequency PNH clones can be found in a good proportion of patients with aplastic anemia (AA) and may appear in association with other bone marrow failure syndromes, such as myelodysplasia or T-cell large granular lymphocyte (LGL) leukemia [6]. PNH may also develop following immunosuppressive therapy for AA [7,8]. All PNH patients to date have been shown to harbor *PIG-A* mutations; the product of this gene is required in an early step in the synthesis of the glycosylphosphatidylinositol (GPI) anchor. Two GPI-anchored proteins (GPI-APs) that protect red blood cells (RBCs) from complement activity, CD55 (DAF: decay-accelerating factor) and CD59 (MIRL: membrane inhibitor of reactive lysis), are lacking on the surface of PNH RBCs, thereby leaving these cells highly sensitive to complement-mediated destruction. The clinical course of PNH is highly variable. Some patients present with only mild symptoms whereas others have life-threatening complications of thrombosis, hemolysis, or marrow failure with infection from neutropenia or bleeding from thrombocytopenia. The disease often has a waxing and waning course, sometimes over 15 years or longer, and it is difficult to predict when a life-threatening complication will occur [9].

Pathogenesis of PNH

The *PIG-A* gene mutation

Numerous studies have elucidated the molecular basis for PNH. The abnormal PNH clone has a defect in the formation of GPI that is part of the anchor proteins on the cell surface. The defect is due to an acquired somatic mutation in the phosphatidylinositol glycan-A (PIG-A) gene of the hematopoietic stem cell [10–12]. The *PIG-A* gene product is required for the first step in the synthesis of GPI-APs [13]; therefore, *PIG-A* mutations block the biosynthesis of the GPI anchor, as shown in the left and central diagrams in Figure 47.1.

Since *PIG-A* is on the X chromosome and males and females have only one active X chromosome per cell (in females, one X chromosome is inactivated through lionization), a single *PIG-A* mutation can generate a PNH phenotype. All other genes involved in GPI anchor biosynthesis are found on autosomes; hence inactivating mutations in these genes would have to occur on both alleles in the same cell, which is highly unlikely. A wide range of somatic mutations throughout the entire coding region of the *PIG-A* gene have been described in PNH patients. There are no true mutational “hotspots,” although exon 2, which contains almost half of the coding region, is the exon where most mutations occur. Most *PIG-A* mutations are small insertions or deletions that result in a frameshift in the coding region and consequently a shortened, non-functional product (reviewed in [14,15]).

PNH clonal evolution

Although the identification of mutations in the *PIG-A* gene has provided a direct explanation of the PNH phenotype in red cells and in other blood cells, it does not explain why and how a *PIG-A* mutant clone expands. To explain this essential component of the pathogenesis of PNH, the following models have been proposed and are supported by experimental or observational studies:

1. *Immune evasion:* PNH cells may evade immune attack, possibly because of a missing cell surface GPI-AP that is the target of the immune attack [16]. This model is attractive as it can explain the close association between AA and PNH; however, no GPI-AP has been shown to be the immunologic target in AA or PNH. Furthermore, GPI-APs are translated in PNH cells but are degraded within the cells in the absence of the GPI anchor [17]; thus, protein epitopes can still be displayed in the context of human leukocyte antigen (HLA) and be immunogenic.
2. *Conditional growth advantage:* The *PIG-A* mutation may confer an intrinsic resistance to apoptosis [18] that becomes more apparent when in the immunologic environment. This also explains the link between AA and PNH. No clear survival advantage has been found under a variety of conditions in the mouse model of PNH [19], but several studies have found that primary GPI-AP-deficient myeloid cells from PNH patients are relatively resistant to apoptosis [18,20–23].
3. *Mutation-driven growth advantage:* A second anti-apoptotic mutation may occur in the PNH clone [24]. Support for this hypothesis is derived from a report of two patients with PNH in whom an acquired rearrangement of chromosome 12 produced ectopic expression of the *HMGA2* gene. However, as argued elsewhere, it is unlikely that a second mutation in the same HSC explains clonal expansion of GPI$^-$ cells in the majority of patients with PNH [25,26].

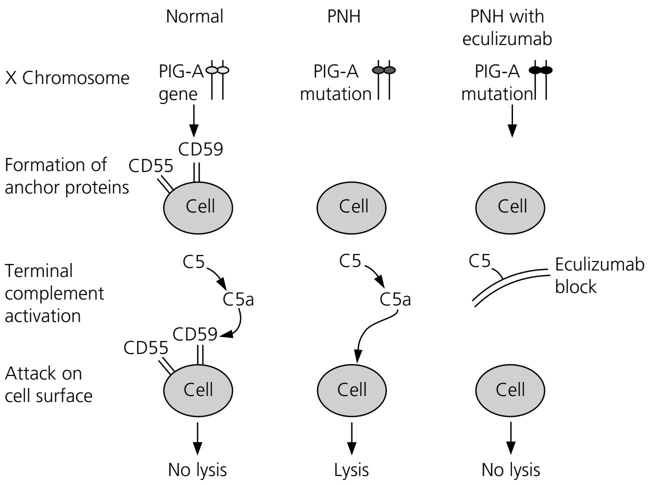

Figure 47.1 Pathway showing the formation of anchor proteins that protect cells from lysis by activated complement in normal individuals, subjects with paroxysmal nocturnal hemoglobinuria (PNH), and the effect of eculizumab to prevent activation of C5 to C5a. C5, fifth component of complement; C5a, activated fifth component of complement; CD55, CD59, anchor proteins; PIG-A, phosphatidylinositol glycan-A gene.

Clinical manifestations

Classifications

The International PNH Interest Group proposed a working classification of PNH as follows [27]:

1 *Classic PNH:* clinical evidence of intravascular hemolysis, no evidence of another defined bone marrow abnormality, a cellular marrow with erythroid hyperplasia and normal/near-normal morphology, without non-random cytogenetic abnormalities.
2 *PNH in the setting of another specific bone marrow disorder:* clinical and laboratory evidence of hemolysis, but also have concomitantly, or have had a history of, a defined underlying marrow abnormality [e.g., AA, myelodysplastic syndrome (MDS)].
3 *Subclinical PNH (PNH-sc):* no clinical or laboratory evidence of hemolysis. Small populations of GPI-AP-deficient hematopoietic cells are detected by very sensitive flow cytometric analysis. PNH-sc is observed in association with bone marrow failure syndromes (e.g., AA, MDS).

Hemolysis

The absence of CD59 (membrane inhibitor of reactive lysis) from the surface of PNH erythrocytes leads to intravascular hemolysis. CD59 blocks the aggregation of C9 into the C5b-8 complex, thereby effectively preventing the formation of the intact membrane attack complex (MAC) [28]. Hemolysis in PNH is chronic, but can be associated with episodic hemolysis (paroxysms) resulting from increases in complement activation due to infections, surgery, strenuous activity, and excessive alcohol intake. PNH patients also experience extravascular hemolysis due to absence of CD55 (DAF) on the surface of RBCs. CD55 [29] functions to accelerate the rate of destruction of membrane-bound C3 convertase. Extravascular hemolysis tends to be less evident in most PNH patients since CD59 deficiency leads more rapid intravascular RBC destruction [30]. However, treatment of PNH patients with the terminal complement inhibitor eculizumab can make the extravascular hemolysis of PNH more conspicuous [31].

Nitric oxide scavenging

Nitric oxide is synthesized in the endothelium and functions to maintain proper vascular and muscle tones and to limit platelet activation. In PNH, intravascular hemolysis generates a large amount of free hemoglobin in serum which serves as a potent scavenger of nitric oxide. The release of erythrocyte arginase into serum during intravascular hemolysis further decreases the substrate (arginine) for nitric oxide synthesis. The resulting deprivation of nitric oxide from tissues is thought to be responsible for a wide range of systemic symptoms in PNH patients, including generalized fatigue, pain, esophageal spasm, male erectile dysfunction, renal impairment, and possibly thrombosis[32].

Thrombophilia

Thrombosis in PNH patients is one of the life-threatening complications, and means to predict which patients are at high risk for thrombosis are needed. Patients with clinical symptoms of abdominal pain, hemoglobinuria, esophageal spasm, and impotence are more likely to have thrombotic events [33]. Geographic differences in the incidence of thrombosis have been observed. Latin Americans and African- Americans are at higher risk than Europeans and other groups. Ethnicity, therefore, is a risk factor for thrombosis in PNH [34]. The pathogenesis of thrombotic events associated with PNH is not well understood.

Complement-mediated hemolysis, impairment of the fibrinolytic system, platelet activation, and leukocyte-derived tissue factors are thought to be responsible [35–37]. Nitric oxide depletion has been associated with increased platelet aggregation, adhesion, and accelerated clot formation. PNH platelets undergo exocytosis of the complement attack complex to repair complement-mediated damage, which results in the formation of microvesicles with phosphatidylserine externalization, a potent in vitro procoagulant. Activation of complement cascade and subsequent generation of C5a significantly upregulates expression of tissue factor (TF), a key initiating component of coagulation cascade [38]. Fibrinolysis may also be compromised in PNH as the PNH blood cells lack the GPI-anchored urokinase receptor. In addition, tissue factor pathway inhibitor (TFPI) has been shown to require a GPI-anchored chaperone protein for trafficking to the endothelial cell surface [39].

The propensity for thrombosis is related to the size of the PNH clone. Among 49 patients with a PNH clone measured in granulocytes, thrombosis occurred in 12 of 22 patients who had more than 61% PNH granulocytes, whereas none of the remaining 27 patients with less than 61% PNH granulocytes had thromboses [33]. Such markers of increased risk of thrombosis in the blood can be of value clinically in identifying which patients are at risk and who could be candidates for anticoagulation and possibly early transplantation.

Association with AA, MDS

An expanded PNH clone is also found in up to 70% of patients with acquired AA, demonstrating a pathophysiologic link between these disorders [40–42]. In contrast to patients with classic PNH, these patients typically have a lower percentage of PNH cells. Acquired AA is an autoimmune disorder, where the target of the immune attack is primitive $CD34^+$ bone marrow progenitors [43,44]. Typically, fewer than 10% of GPI-AP-deficient granulocytes are detected in AA patients at diagnosis, but occasional patients may have larger clones [40]. DNA sequencing of the GPI-AP-deficient cells from AA patients reveals clonal *PIG-A* gene mutations [45]. Although most AA patients exhibit no signs or symptoms of PNH early in the natural history of their disease when the PNH clone size is small, many, but not all, will experience further expansion of the *PIG-A* mutant clone and progress to classic PNH. GPI-AP-deficient cells have also been reported in patients with MDS [40,45]. Patients with MDS who are reported to have small PNH populations tend to be classified as having refractory anemia and often have the following characteristics: a hypocellular marrow, HLA-DR15 positivity, normal cytogenetics, moderate to severe thrombocytopenia, and a high likelihood of response to immunosuppressive therapy [45,46].

Natural history and prognosis

The issues that confound recommendations for transplantation for PNH center both on the heterogeneous presentation and natural history and on its close association with marrow failure syndromes. In a study by Hillmen et al., a group of 80 consecutive patients with PNH in the United Kingdom was followed and it was found that the median survival after diagnosis was 10 years, with 22 patients (28%) surviving for 25 years [3]. Sixty patients have died; 28 of the 48 patients for whom the cause of death is known died from either venous thrombosis or hemorrhage. Thirty-one patients (39%) had one or more episodes of venous thrombosis during their illness. Of the 35 patients who survived for 10 years or more, 12 had a spontaneous clinical recovery. A study of 220 patients with PNH from the registry of the French Society of Hematology [47] showed a median survival of 12 years for the entire cohort, and identified risk factors associated with a worse outcome: (1) age older than 55 years; relative risk (RR) of death 4.0; (2) occurrence of thrombosis (regardless of location; RR 10.2); (3) progression to pancytopenia (RR 5.5); (4) transformation to MDS or acute leukemia (RR 19.1); and (5) thrombocytopenia at diagnosis (RR 2.2).

The French group recently analyzed an expanded cohort of 460 PNH patients diagnosed in 58 French hematologic centers from 1950 to 2005 [48], aiming to study the natural history of PNH clinical subcategories (classic PNH and AA-PNH syndrome). After a median follow-up time of 6.8 years, the median survival time was 22 [standard error (SE) 2.5] years. The study identified 113 patients with classic PNH, 224 patients with AA-PNH syndrome, and 93 (22%) intermediate patients who did not fit within these two categories. At presentation, classic PNH patients were older, with more frequent abdominal pain, and displayed higher levels of GPI-AP-deficient granulocytes. A time-dependent improved survival was observed. In classic PNH, diagnoses before 1986 [hazard ratio (HR) 3.6, $p = 0.01$] and increasing age ($p < 0.001$) were associated with worse survival prognoses, whereas use of androgens within the first year after diagnosis was protective (HR 0.17, $p = 0.01$). Transfusions before 1996 (HR 2.7, $p = 0.007$) led to lower survival rates in patients with AA-PNH syndrome, whereas immunosuppressive treatment was associated with better outcomes (HR 0.33, $p = 0.03$). Evolution to thrombosis affected survival in both subcategories (classic PNH, HR 7.8, $p < 0.001$; AA-PNH syndrome, HR 33.0, $p < 0.001$). Evolution to bicytopenia or pancytopenia for classic PNH (HR 7.3, $p < 0.001$) and malignancies for AA-PNH syndrome (HR 48.8, $p < 0.001$) were associated with worse outcomes. It was concluded that although the clinical presentation and prognosis factors are different, classic PNH and AA-PNH syndrome present roughly similar outcomes, affected mainly by complications.

Diagnosis

A diagnosis of PNH should be considered when a patient presents with non-autoimmune hemolytic anemia or AA. It should also be included in the differential diagnosis of individuals presenting with a life-threatening thrombosis or with recurrent thromboses (Table 47.1). The time-honored tests to diagnose patients in whom PNH is suspected have been the sugar water hemolysis and Ham's tests. However, these tests are positive only when abnormal cells remain in circulation after a major hemolytic episode.

Table 47.1 Clinical and laboratory characteristics of paroxysmal nocturnal hemoglobinuria (PNH), AA, and myelodysplasia

	Normal control	PNH	Aplastic anemia	Myelodysplasia
Clinical features				
Aplastic/cytopenia	–	+	+	+/–
Non-autoimmune hemolytic anemia	–	+	–	–
Thrombosis	–	+	–	–
Laboratory findings				
Ham's test on RBCs	–	+	+/–	–
Flow cytometry detection of CD55 and CD59 on RBCs and leukocytes	+	–	+/–	+
Aerolysin detection of PNH type II and III cells	–	+	+/–	–

The recognition of the abnormalities of expression of other anchor proteins including CD14 and CD55 on affected monocytes, the expression of anchor proteins CD16, CD24, CD59, and CD66b on neutrophils, and that of CD24 and CD59 on lymphocytes makes it possible to establish the diagnosis by flow cytometry of cells that remain in circulation [49,50]. In contrast to GPI-AP-deficient RBCs, the life span of PNH granulocytes is normal. Therefore, the proportion of abnormal granulocytes more accurately reflects the PNH clone size and is not affected by RBC transfusions. For initial evaluation, quantitation of at least two GPI-anchored proteins is recommended to exclude the possibility that the clinical process is a consequence of an inherited or acquired isolated deficiency of a single GPI-AP.

More sensitive tests have been developed that raise questions about the relationship between the two different diseases [51]. Aerolysin is a toxin that binds to cells via the anchor proteins encoded by the *PIG-A* gene. Since PNH red cells cannot bind the toxin, they survive in an aerolysin-based assay [fluorescent aerolysin (FLAER) assay]. Using this assay, residual PNH cells can be detected in samples from PNH patients but not in cells from patients with myelodysplasia or in normal control samples. However, as many as 60% of the cells obtained from patients who have idiopathic AA and not PNH by flow cytometry before treatment with the aerolysin toxin show characteristics of PNH after treatment [51,52] (Table 47.1). This sensitive test indicates that previously undetectable PNH cells of different lineages circulate in patients with untreated AA, and points to the possibility of clonality in the early stages of AA.

Non-transplant treatment of PNH

There are no widely accepted evidence-based indications for treatment of PNH. In classic PNH, eculizumab should be considered for patients with disabling fatigue, thromboses, transfusion dependence, frequent pain paroxysms, renal insufficiency, or other end-organ complications from disease. Watchful waiting is appropriate for asymptomatic patients or those with mild symptoms. In patients with AA-PNH, therapy should be directed towards the underlying bone marrow failure; patients who meet criteria for severe AA should be managed with either allogeneic bone marrow transplantation (BMT) or immunosuppressive therapy depending on the age of the patient and the availability of a suitable HLA-matched sibling donor. Immunosuppressive therapy using antithymocyte globulin (ATG)/cyclosporine does not eradicate the abnormal PNH clone, and patients may continue to be symptomatic from the disease [53–56]. In a small number of patients, high-dose cyclophosphamide (CY) without marrow infusion has resulted in autologous marrow recovery without persistence of the PNH clone [57].

Eculizumab

By far the most significant advance in non-transplant therapy for PNH is the recent development of eculizumab, a humanized monoclonal antibody against the complement protein C5, thereby blocking terminal complement activation as shown in the right-hand diagram in Figure 47.1. Eculizumab prevents hemolysis in patients with PNH. In a randomized placebo-controlled, multicenter phase III trial, 21 of 43 patients assigned to eculizumab achieved stabilization of hemoglobin levels and transfusion independence, whereas none of 44 patients assigned to placebo achieved those outcomes. Eculizumab reduced intravascular hemolysis by 86% and was associated with improved quality of life measures [58]. After treatment, serum LDH concentration returns to normal or near normal, with approximately half to two-thirds of patients achieving transfusion independence; however, mild to moderate anemia, hyperbilirubinemia, and reticulocytosis persist in essentially all treated patients.

Accumulating data also suggest that eculizumab may protect against other complications of hemolytic PNH, such as deteriorating renal function, pulmonary hypertension, and thromboembolism [59–61]. Treatment with eculizumab appears to have a favorable impact on survival, because a recent study of 79 patients treated between 2002 and 2010 showed the same survival rates as those of age- and gender-matched controls from the general population [48,62]. However, the impact of eculizumab on survival cannot be accurately quantified, owing to the lack of a control patient group in that study.

There are, however, limitations in the treatment with eculizumab; it is expensive (~$400,000/year in the United States) and has no effect on either the underlying stem-cell abnormality or on the associated BM failure. Consequently, treatment must continue indefinitely and leukopenia, thrombocytopenia, and reticulocytopenia, if present, persist. Suboptimal response to treatment with eculizumab may occur as a result of breakthrough intravascular hemolysis (i.e., increases in LDH and development of constitutional symptoms) near the end of a treatment cycle, inappropriately low erythropoietin levels, decreased iron stores, and/or extravascular hemolysis as C3 was found bound to a portion of the PNH erythrocytes (i.e., the CD59-deficient population after treatment with eculizumab) [30].

Corticosteroids

Corticosteroids as treatment for both chronic hemolysis and acute hemolytic exacerbations is a subject of debate. Nonetheless, some patients appear to respond rapidly and dramatically to glucocorticoids (given in the dosage range 0.25–1.0 mg/kg/day of prednisone). The rapid response (often within 24 hours of initiating therapy) suggests that complement inhibition accounts for the antihemolytic activity of glucocorticoid therapy. Such an effect could be direct (the result of inhibition of the activity of some component of the alternative pathway of complement) or indirect (the result of damping a process, such as inflammation, that stimulates activation of complement). Hence the main value of corticosteroids may be in attenuating acute hemolytic exacerbations. Under these circumstances, brief pulses of prednisone may reduce the severity and duration of the crisis while avoiding the untoward consequences associated with long-term use.

Androgens

Androgen therapy, either alone or in combination with steroids, has been used successfully to treat the anemia of PNH. As with glucocorticoids, the mechanism by which androgenic steroids ameliorate the anemia of PNH is not fully understood, although the rapid onset of action is consistent with complement inhibition [63].

Iron replacement

Patients with PNH frequently become deficient in iron as a result of both hemoglobinuria and hemosiderinuria. Clinically important iron loss from hemosiderinuria can occur even in the absence of gross hemoglobinuria. Replacement is often associated with exacerbation of hemolysis, regardless of the route of administration [63,64]. Compared with parenteral replacement, oral administration of iron may be accompanied by less severe hemolytic exacerbations, but urinary iron loss may be so great that repletion cannot be achieved through this mechanism. If a hemolytic exacerbation occurs in the setting of iron repletion, the episode can be controlled by treatment with corticosteroids or androgens or by suppression of erythropoiesis by transfusion.

Transfusion

In addition to increasing the hemoglobin concentration, transfusion may ameliorate hemolysis by suppressing erythropoiesis. Concerns about inducing a hemolytic exacerbation as a consequence of infusion of small amounts of donor plasma that may contaminate RBC preparations appear unwarranted [65]. However, hemofiltration is recommended to prevent transfusion reaction arising from the interaction between donor leukocytes and recipient antibodies. Transfusion-related iron overload from chronic transfusion may be delayed in patients with PNH due to iron loss from hemoglobinuria/hemosiderinuria [64]. However, iron overload remains a concern in patients who require chronic transfusion when the anemia is primarily a consequence of marrow failure rather than hemolysis.

Transplantation for PNH

Before the availability of eculizumab, the primary indications for transplantation for PNH were bone failure, recurrent life-threatening thrombosis, and uncontrollable hemolysis. The last process can be eliminated by treatment with eculizumab and the thrombophilia of PNH may also respond to inhibition of intravascular hemolysis by eculizumab [59]. Nonetheless, transplantation is the only curative therapy for PNH, and the availability of molecularly defined, matched unrelated donors, less toxic conditioning regimens, reductions in transplantation-related morbidity and mortality, and improvements in post-transplantation supportive care make this option a viable alternative to medical management. The decision as to who should receive a transplantation and when it should be performed is complex.

Hematopoietic cell transplantation (HCT) from an HLA-identical sibling for a patient with PNH was first reported in 1973 [66]. This patient was found to have PNH at the time of presentation of severe AA and had a positive sucrose hemolysis or Ham's test. In subsequent reports, most patients had life-threatening disease from

[a] Ref. [71] contains cases previously reported in [66,67,70].

[b] One allogeneic recipient (patient 8; Table 47.3) had a return of the PNH clone 2.7 years after transplantation and is asymptomatic.

marrow aplasia, and hemolysis played a less important role at the time of HCT [67–70]. Subsequently, patients with hemolysis or thrombosis were evaluated for transplantation. Overall, the number of individuals who have been transplanted is small (Table 47.2).

The experience in Seattle with transplantation for nine patients was summarized in 1992 [71]. Subsequently, 19 additional patients have been transplanted, and the results are updated in Table 47.3. Among the total of 28 patients, 12 presented with the severe AA phase of PNH and had severely hypocellular marrows. The remaining 16 patients presented with hemolysis or thrombosis and had moderately cellular to hypercellular marrows. One of these (patient 28) also had documented thromboses associated with the presence of the factor V Leiden abnormality. Data from Table 47.3 are summarized in Table 47.4.

Conditioning for grafting of the patients with AA who had HLA-identical sibling donors consisted of 200 mg/kg CY with or without ATG in five patients, and 16 mg/kg busulfan (BU) with 60 mg/kg CY in two patients. One of these patients with AA received two grafts from the same donor. The patient with AA and the haploidentical parental graft was conditioned with 120 mg/kg CY and 1200 cGy total body irradiation (TBI). The syngeneic recipient with AA received an infusion of marrow without conditioning. One patient with AA received an unrelated umbilical cord blood HCT after myeloablative conditioning with ATG, BU, and 1350 cGy TBI. Two patients received matched unrelated peripheral blood stem cells following conditioning with fludarabine 90 mg/m^2 body surface area and 200 cGy TBI.

The conditioning regimens for the HLA-identical siblings with thrombotic or hemolytic presentations of PNH consisted of BU CY plus ATG in four patients and BU CY in three patients. One patient with a history of idiopathic chronic myelofibrosis, hemolysis, and pancytopenia received an HLA-identical sibling peripheral blood stem-cell graft after BU, fludarabine 120 mg/m^2 body surface area, and ATG. The recipients of the parental donor graft and the child donor graft received BU CY plus ATG, or BU CY, respectively. The mismatched sibling received BU CY and ATG. Among three recipients of unrelated donor marrow, two were conditioned with BU CY and ATG, and one with BU CY. One patient received CY, ATG, and 1350 cGy TBI for an unrelated umbilical cord blood graft. The syngeneic marrow recipient did not receive conditioning.

Fifteen of the 28 patients developed acute graft-versus-host disease (GVHD) (10 grade II, three grade III, and two grade IV), and 10 subsequently developed clinically extensive chronic GVHD. PNH recurred 9–17 years after transplant in both syngeneic recipients and 2.7 years after transplantation in one allogeneic recipient [71]. Fourteen patients died. The causes of death included GVHD complicated by infection in two patients, fungal pneumonia in two patients, and a gastrointestinal bleed in one patient. The last patient had thromboses of the portal and splenic veins from PNH, which led to bleeding varices. One patient rejected the haploidentical parental graft and died of pulmonary hemorrhage shortly after a second transplant from another haploidentical family member. One patient died of a post-transplant lymphoproliferative disorder 169 days after an unrelated umbilical cord blood transplant. One died from human immunodeficiency virus (HIV) infection 9.3 years after transplantation. One died of hepatitis C 14.6 years after transplant, and one syngeneic recipient died 25.2 years after transplantation as a result of complications of a liver transplant for hepatitis C. One developed myelodysplasia in the donor cells 26.9 years after transplant and had a second successful myeloablative transplant from a different HLA-identical sibling following BU/CY, but committed suicide about 1 year later, 28.5 years after the first transplant. One each died of probable cerebral hemorrhage, myocardial infarction, and respiratory failure of unknown cause 176 days, 1.7 years, and 4.1 years, respectively, after HCT. Fourteen patients are surviving more than 1–35 (median 7.6) years after transplantation. Six of these individuals are well, and eight have clinically extensive chronic GVHD.

These results show that patients with the AA presentation of PNH do well; none of the eight AA patients who received HLA-identical sibling or syngeneic grafts died from the complications of transplantation (Figure 47.2). One of these died later from HIV infection before the era of blood screening for HIV. In contrast, eight of the 16 patients who received a transplant from any type of donor for the hemolytic or thrombotic presentations of PNH died. Five of these patients died within 120 days after transplantation of complications from GVHD with non-fungal infection, fungal infection, or variceal bleeding. Three died later, one each of hepatitis C, post-transplant lymphoproliferative disorder, and respiratory failure presumably related to chronic GVHD.

The International Bone Marrow Transplant Registry has reported the results of 57 patients with PNH who were transplanted at 31 different centers [72]. Thirty-nine of these patients presented with PNH as the only diagnosis. Sixteen evolved from PNH into an AA presentation by the time of HCT, and two developed PNH syndrome after initially presenting with AA. The donors were HLA-identical siblings in 48 cases, syngeneic donors in two cases, a haploidentical family member in one case, and HLA phenotypically identical, unrelated donors in six cases. These patients received conditioning consisting of BU/CY for 30 patients, CY/TBI for 12,

GVHD, graft-versus-host disease.

HCT donor: 1Ag, 1 antigen; haplo, haploidentical; HLA ID SIB, human leukocyte antigen-identical sibling; MM, mismatched; PBSC, peripheral blood stem cells; Unrel, unrelated.

Paroxysmal nocturnal hemoglobinuria presentation: A, AA; H, hemolysis; ICMF, idiopathic chronic myelofibrosis; T, thrombosis.

Conditioning regimen: ATG, antithymocyte globulin; BC, donor buffy coat; BU, busulfan; CY, cyclophosphamide; FLU, fludarabine; PA, procarbazine + ATG; TBI 1350, 1350 cGy total body irradiation; TBI 200, 200 cGy total body irradiation.

GVHD acute grade/chronic: Clin Ext, clinical extensive; NA, not applicable; Subclin, subclinical.

Status: A, alive; D, dead.

limited field irradiation and CY for 11, and CY alone for three patients. One identical twin recipient did not receive any pretransplant conditioning. GVHD prophylaxis consisted of methotrexate or cyclosporine plus methotrexate in 39 patients, and cyclosporine plus corticosteroids in 11 patients. Six patients received T-cell-depleted grafts, and one identical twin recipient did not receive prophylaxis.

Graft failure occurred in 11 of 48 patients evaluable for engraftment. Of those with engraftment, 34% developed grade II or greater acute GVHD, and 33% of patients surviving beyond 90 days developed chronic GVHD. Overall, 30 of the 57 patients survived. Among those 48 patients receiving HLA-identical sibling grafts, 27 (56%) survived compared with one survivor among seven patients (14%) receiving HLA-non-identical family member or unrelated donor grafts. Six patients in three reports had matched sibling donors for hemolytic or aplastic presentation, and five survived transplantation with myeloablative conditioning regimens without PNH recurrence [81–83].

One report described three patients with the AA presentation of PNH given unrelated donor bone marrow grafts following T-cell depletion of marrow. The post-transplant course was complicated by an Epstein–Barr virus-positive lymphoproliferative disorder that responded to cytotoxic T-cell therapy specific for this virus. Another patient had venocclusive disease and another severe hemolytic uremic syndrome and hemorrhagic cystitis. However, they all recovered and were alive without PNH 2.5–5.1 years after transplantation [78]. Three reports describe seven unrelated donor transplant recipients with myeloablative conditioning regimens for aplastic or hemolytic presentations of PNH, five of whom survived without subsequent recurrence of their disease [80,81,86].

These data suggest that survival after HCT for the aplastic phase of PNH using HLA-identical sibling donors is fairly good. However, transplantation is successful in only about half of the cases with non-aplastic presentations of PNH using HLA-identical sibling donors. Results using partially matched family member donors are poor. Finally, although the results using matched unrelated donors are encouraging, the reports are few.

A recent study by the European Group for Blood and Marrow Transplantation (EBMT) evaluated the outcome and risk factors affecting survival after allogeneic HCT in the largest cohort ever studied of 211 PNH patients [89]. They also conducted a formal survival comparison of this cohort of transplanted PNH patients

Table 47.4 Summary of patients in the Seattle transplant program ($n = 28$): donor type, conditioning regimen, and survival

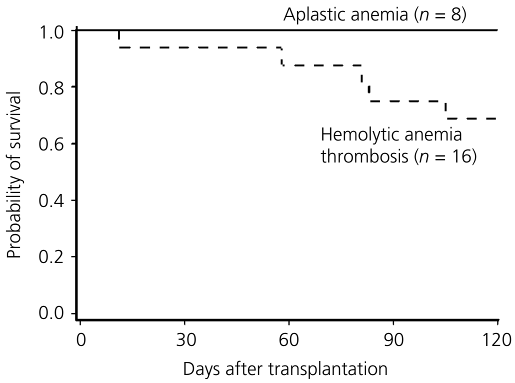

Figure 47.2 Survival 4 months after transplant. The solid line represents eight patients with the AA presentation of paroxysmal nocturnal hemoglobinuria (PNH) who had HLA-identical sibling or syngeneic donors compared with 16 patients with the hemolytic or thrombotic presentations with any type of donor (dashed line).

with a matched cohort of non-transplanted PNH patients reported to, and previously published by, the French Society of Hematology. After a median follow-up of 5 years, the 5-year overall survival rate ± SE (%) was 68 ± 3 in the transplanted group (54 ± 7 in case of thromboembolism, 69 ± 5 in case of AA without thromboembolism, and 86 ± 6 in case of recurrent hemolytic anemia without thromboembolism or AA). Only thromboembolism indication for transplantation was associated with worse outcome ($p = 0.03$). The study identified 24 pairs of transplanted and non-transplanted patients with thromboembolism for the matched comparison, with worse overall survival for the transplanted patients {HR 10.0 [95% confidence interval (CI) 1.3–78.1], $p = 0.007$}. This was confirmed by the global matching procedure ($p = 0.03$). Concerning AA without thromboembolism, 30 pairs were identified for matched comparison. Not significantly worse overall survival was observed for transplanted patients [HR 4.0 (95% CI 0.9–18.9), $p = 0.06$]. The global matching procedure was not feasible. One of the conclusions of the authors was that allogeneic stem-cell transplantation is probably not a suitable treatment option for life-threatening thromboembolism in PNH.

Transplants following reduced-intensity conditioning

Because of reduced toxicity, non-myeloablative or reduced-intensity conditioning regimens are appealing. The reduced-intensity conditioning regimens often used may be insufficient for sustained donor engraftment in patients with non-aplastic presentations because even those syngeneic recipients of marrow for the aplastic phase of PNH required conditioning regimens to achieve sustained donor engraftment (Table 47.2) [67,68,71,72,75–77,79]. Furthermore, syngeneic recipients who did not receive pre-transplant conditioning eventually had a return of PNH disease years later [70,71].

Except for one patient, recipients of allogeneic stem cells had sustained elimination of the disease (Table 47.3) [71]. These results suggest that a graft-versus-PNH type of effect in either a myeloablative or reduced-intensity allogeneic transplant procedure makes an important contribution toward eliminating the PNH clone. There have been reports of individual cases treated by reduced-intensity HCT approaches with successful elimination of PNH that support the idea that immunologically based eradication of PNH cells is possible following reduced-intensity conditioning regimens (Table 47.2). Further studies of the reduced-intensity approach are warranted, especially for patients who cannot undergo conventional HCT because of an increased risk of transplant-related mortality due to pre-transplant organ dysfunction.

Use of eculizumab during HCT

PNH patients who are deemed candidates for allogeneic HCT may have been treated with eculizumab prior to HCT. The question may arise of whether eculizumab would be required or helpful in the management of PNH during HCT. There is no published evidence to support the use of eclulizumab; however, for patients with a large PNH clone, there is a risk of significant intravascular hemolysis, which is potentially massive due to withdrawal of eculizumab. Active hemolysis can be associated with renal dysfunctions and thrombosis, and therefore may adversely impact on the transplant outcomes. Hence it would be reasonable to consider the use of continued eculizumab until donor-derived hematopoiesis is established with none or minimal residual PNH cells.

In addition, Kwan et al. recently reported that total body irradiation caused upregulation and activation of alternative pathway complement components by recipient antigen-presenting cells (APCs) [90]. Allo-HCT with DASF-null (*Daf1–/–*) host BM and *Daf1–/–* donor lymphocytes led to exacerbated GVHD outcome and resulted in splenic and organ-infiltrating T-cell expansion. T cells deficient in C3a receptor (C3aR) and/or C5a receptor (C5aR) responded weakly in allogeneic hosts and exhibited limited ability to induce GVHD. The study also showed that pharmacological C5aR blockade reduced GVHD morbidity.

Autologous transplantation for PNH

An interesting hypothesis has been put forward by Musto et al. [91]. They demonstrated that flow cytometry could select CD34$^+$/CD59$^+$ cells from PNH patients who had a mixed population of circulating normal and abnormal cells. If these cells do not bear the mutation in the *PIG-A* gene, a rationale to mobilize and select autologous normal hematopoietic stem cells for autologous transplantation exists, although no autologous transplant cases have been reported [56].

Finally, indications for bone marrow/stem cell transplantation and management issues for patients with PNH are presented in Table 47.5.

Table 47.5 Bone marrow/stem cell transplantation for patients with PNH

Indications for consideration of transplantation
- Bone marrow failure
  - Decision on transplantation is based on the severity and prognosis of underlying marrow abnormality (e.g., AA, MDS)[a]
- Major complication of PNH[b,c]
  - Recurrent, life-threatening thromboembolic disease
  - Refractory, transfusion-dependent hemolytic anemia

PNH-specific transplant-related issues
- Conditioning regimens
  - Cyclophosphamide/ATG (or other regimens used for AA)
- For patients with Classic PNH
  - more myeloablative regimen is indicated[d] (i.e. BU CY, BU FLU, FLU MEL). Additional investigation is required to define the role of non-myeloablative regimens
- Syngeneic twin transplants
  - a myeloablative conditioning regimen is recommended to prevent recurrence of PNH

Other complications/outcomes
- There are no PNH-specific adverse events associated with transplantation; severe acute graft-versus-host disease (GVHD) occurs in more than one-third of the patients and the incidence of chronic GVHD is roughly 35%. Overall survival for unselected PNH patients who undergo transplantation using an HLA-matched sibling donor is in the range 50–60%
- Consider eculizumab during BMT (i.e. until donor engraftment) to prevent withdrawal hemolysis

[a] If the dominant clinical abnormalities are a consequence of bone marrow failure (e.g., hypoproliferative anemia, neutropenia with recurrent infections, thrombocytopenia with major bleeding complications), the decision to recommend transplantation should be based on guidelines for management of the specific marrow failure syndrome.

[b] Factors including age, comorbid conditions, availability of an HLA-matched sibling donor, and time from initial diagnosis should be considered before recommending transplantation for major complications of PNH.

[c] The availability of new treatment options (e.g., eculizumab) may influence the decision to recommend transplantation.

[d] Radiation or busulfan based.

Conclusion

The diagnosis of PNH alone should not be the sole indication for HCT therapy. Defining the risk of a fatal complication in an individual PNH patient is still the most important determination to make before recommending HCT. Eculizumab reduces the risk of hemolysis although it is unlikely it will affect the aplastic phase. Accumulating evidence suggests that eculizumab may reduce the risk of thrombotic complications and may improve the survival outcome of this disease.

When the patient has a life-threatening presentation with AA and an HLA-identical sibling or identical twin donor is available, HCT is recommended. Unrelated donors have been used to achieve successful grafts in patients with idiopathic AA, and HCT with a matched, unrelated donor for the life-threatening aplastic phase of PNH is warranted, although the experience is small. Reduced-intensity conditioning for HCT should be explored further, especially for patients with severe PNH who cannot tolerate a full myeloablative transplant due to comorbid medical conditions. In all other phases of disease, the care should be supportive, and transplantation should be performed when the disease becomes life threatening, or reliable predictors are developed to identify which patients with the non-aplastic phases of PNH are at particularly high risk of death from PNH.

CHAPTER 48

Hematopoietic Stem Cell Transplantation for Chronic Myeloid Leukemia

Jerald P. Radich[1] **and Ravi Bhatia**[2]
[1] Fred Hutchinson Cancer Research Center, Seattle, WA, USA
[2] University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

Chronic myeloid leukemia (CML) is a malignant disorder of hematopoiesis resulting from the clonal expansion of a primitive hematopoietic cell. At the outset of disease, the CML stem cell retains the capacity to differentiate, leading to marked marrow hyperplasia and increased numbers of myeloid cells and platelets in the peripheral blood. The natural history of untreated CML is a relatively benign chronic phase (CP) lasting on average approximately 3–5 years followed by an accelerated phase (AP) lasting several months and then eventually terminating in a rapidly fatal blast crisis (BC).

CML is relatively rare, with an incidence of about two cases per 100,000 per year [1], yet it can be argued that it is the best example of "bench to bedside" in oncology. Consider these major milestones: first, CML was the first malignant disease found to be consistently associated with a specific cytogenetic abnormality, the Philadelphia (Ph) chromosome; second, it was the first leukemia where transplantation became the initial curative option; third, it was the first (and best) example of "targeted" therapy with the use of tyrosine kinase inhibitors.

Nowell and Hungerford in 1960 [2] described the presence of a small chromosome in metaphase preparations of marrows from patients with CML. This abnormal chromosome, termed the Philadelphia chromosome (after the city where it was discovered), was later shown by Rowley to be the result of a translocation between chromosomes 9 and 22 [t(9; 22)(q34;q11)] [3]. The translocation is the fusion of the *BCR* (breakpoint cluster region) gene on chromosome 22 to the *ABL* (Abelson leukemia virus) gene on chromosome 9, and results in the production of an abnormal BCR-ABL fusion protein, which is a constitutively active cytoplasmic tyrosine kinase [4,5]. Thus, the unique BCR-ABL translocation serves as both a target of therapy (with the suppression of ABL by tyrosine kinase inhibitors) and monitoring [of the Ph by cytogenetics, BCR-ABL DNA by fluorescence in situ hybridization (FISH), or BCR-ABL mRNA by reverse transcriptase polymerase chain reaction (RT-PCR)].

Without therapy, CML evolves from a CP to an AP and eventually to BC. Various definitions of AP have been developed. Two of the more commonly employed are those of Sokal et al. and the International Bone Marrow Transplant Registry (IBMTR) [6] (Table 48.1). In general, AP is characterized by symptoms of fever, night sweats, weight loss, bone pain, difficulty in controlling counts using conventional therapy, increased numbers of blasts and early myeloid cells in marrow and peripheral blood, and evidence of karyotypic evolution. The most common cytogenetic changes associated with disease evolution are an additional Ph chromosome, trisomy 8, isochrome i(17q), and trisomy 19. Blast crisis has been defined as having more than 30% blasts and promyelocytes in the bone marrow or peripheral blood, or the development of extramedullary blastic infiltrates, although a reclassification by the WHO has lowered the blast cutoff to 20%. In approximately two-thirds of patients, the blasts are predominately myeloid, whereas in the remaining one-third the blasts have a lymphoid phenotype [6,7].

A number of prognostic scoring systems have been developed with the goal of predicting the length of chronic phase in individual patients, the best known and widely used is by Sokal et al. [6]. In an algorithm, spleen size, percentage of circulating blasts, platelet count, and age were identified as prognostic factors for chronic phase patients. However, the Sokal scale was based on therapies considered archaic today (busulfan, splenectomy), and newer systems for patients treated with interferon resulted in newer prognostic scoring systems [8].

The past: allogeneic hematopoietic cell transplantation as curative therapy in CML

Tyrosine kinase inhibitors (TKIs) have replaced transplantation as front-line therapy, but it must be remembered that before TKIs, allogeneic transplantation of CML was a profound success, particularly in CP. Indeed, CML was unique in that before TKIs, allogeneic transplantation was offered as soon as possible to patients with available donors (initially matched related, and later unrelated donors). To understand the place of transplantation in the modern era of TKI therapy, it is useful to review the outcomes of transplantation, and the factors that influence its effect.

Phase of disease

As with all treatments of CML, outcomes are far superior for hematopoietic cell transplantation (HCT) for patients in chronic phase compared to advanced phase disease. Studies by the Seattle, Hammersmith, and German consortium groups show 3–5-year survival rates of 80–90% for patients treated in CP (Figure 48.1) [9–11] A report on long-term outcomes of 2444 CML patients in CP who receive allogeneic myeloablative HCT between 1978 and 1998 and had survived in continuous complete remission for at

least 5 years confirms the excellent outcome for these patients [12]. Overall survival rates at 15 years were 88% for sibling HCT and 87% for unrelated donor HCT, with corresponding cumulative incidences of relapse of 8 and 2%, respectively. In comparison with age-, race-, and gender-adjusted normal populations, the mortality of HCT recipients was significantly higher until 14 years post-HCT; thereafter, mortality rates were similar to those of the general population.

Outcomes in advanced phase disease (AP and BC) are inferior to CP, with the 4-year probabilities of overall survival (OS) and event-free survival (EFS) being 49 and 43%, respectively [13,14]. A study comparing outcomes of imatinib versus allogeneic HCT for AP CML showed similar survival in “low-risk” patients (those without adverse prognostic factors of disease duration >12 months, hemoglobin <10 g/L, and peripheral blood blasts >5%), but allogeneic HCT conferred a significant survival advantage for patients with these adverse prognostic factors [15]. In virtually all studies, the outcome of transplantation for patients in BC is very poor, because of both a high risk of disease recurrence and a high incidence of transplant-related deaths with survival of approximately 20% or less. A report from the Center for International Blood and Marrow Transplantation Research (CIBMTR) for 449 allogeneic HCTs performed from 1999 to 2004 in advanced phase CML confirmed that disease stage remained the strongest determinant of transplant outcomes, even in the imatinib era [16].

Table 48.1 Definition of accelerated phase chronic myeloid leukemia

Sokal criteria	IBMTR criteria
Peripheral blood or marrow blasts ≥5%	Leukocyte count difficult to control with conventional therapy
Basophils >20%	Rapid doubling time of leukocytes (<5 days)
Platelet count ≥1000 × 10^9/L despite adequate therapy	Peripheral blood or marrow blasts ≥10%
Karyotype evolution	Peripheral blood or marrow blasts plus promyelocytes ≥20%
Frequent Pelger–Huet-like neutrophils; nucleated erythrocytes, megakaryocytic nuclear fragments	Peripheral blood basophils and eosinophils ≥20%
Marrow collagen fibrosis	Anemia or thrombocytopenia unresponsive to therapy
Anemia or thrombocytopenia unrelated to therapy	Persistent thrombocytosis
Progressive splenomegaly	Karyotypic evolution
Leukocyte doubling time <5 days	Progressive splenomegaly
Fever not otherwise explained	Development of chloromas or myelofibrosis

IBMTR, International Bone Marrow Transplant Registry.

Ablative preparative regimens

The majority of patients treated in the early 1980s received a preparative regimen of 120 mg/kg cyclophosphamide (CY), followed by total body irradiation (TBI) of 2.0 Gy on each of six successive days. Subsequent studies showed that regimens containing 16 mg/kg busulphan (BU) administered over 4 days combined with 60 mg/kg CY on each of two successive days showed no differences between the CY–TBI and BU–CY treatment groups in survival at 3 years (80% for both), relapse (13% for both), or EFS (68% for CY–TBI and 71% for BU–CY)[17]. An update in 2002 shows OS of 78% at 10 years with BU–CY vs. 64% with CY–TBI [18]. The advance of BU monitoring to achieve a steady-state BU concentration at 900–1200 ng/mL was shown in a study of CP patients transplanted with human leukocyte antigen (HLA)-identical relatives, to offer a 3-year survival of 86%, a relapse rate of only 8%, and a non-relapse mortality rate of 14% [10]. Other preparative regimens have also been reported to provide excellent disease control with acceptable toxicities in the treatment of CP CML, including the regimen of TBI plus etoposide reported by the City of Hope National Medical Center and Stanford University groups and the use of CY plus 500 cGy TBI given as a single dose at a high dose rate [19].

Reduced-intensity conditioning (RIC) in CML

Given the power of the graft-versus-leukemia (GVL) effect following standard transplantation for CML, reduced-intensity or non-ablative transplant approaches have been developed in an attempt to avoid the toxicities of high-dose preparative regimens while retaining the potentially powerful GVL effects. These approaches (discussed in more detail in Chapter 20) are of particular relevance for patients with CML given that their median age at diagnosis is 67 years. The Seattle consortium published results with a non-myeloablative (NMA) regimen of Flu–TBI or 2 Gy TBI in 24 patients with CML first CP, second first CP, or AP. All patients received peripheral blood progenitor cells (PBPCs) from matched related donors [20]. Five of 25 patients died from non-relapse mortality (NRM), and the 100-day NRM rate was 4%. The 2-year estimates of OS were 70% for patients in first CP and 56% for patients beyond first CP. However, results using unrelated donors were not as initially encouraging because of high rates of graft rejection (45%). Investigators at Hadassah-Hebrew University Hospital published results for a younger cohort of patients (median age 35 years) using an RIC regimen of Flu 180 mg/m^2, oral BU 8 mg/kg, and ATG 20–40 mg/kg, in 24 patients with CP CML. Nineteen patients received minimal

Reproduced with permission of the American Society of Hematology.

residual disease (MRD) monitoring and five received unrelated donor PBPCs [21]. The 100-day NRM was 0% and there were only three mortalities in the series, all secondary to GVHD. The estimated 5-year OS and relapse-free survival (RFS) were 85%. At a median of 42 months from HCT, all patients had a complete molecular response.

The European Group for Blood and Marrow Transplantation (EBMT) has reported results on 186 patients with CML (median age 50 years) who received RIC [22]. Patients with all stages of CML were included, with various RIC regimens. In addition, there was a mix of stem-cell product source [PBSC vs. bone marrow (BM)], and donors (HLA-matched and -mismatched related and unrelated donors). The 100-day NRM was 6.1% and the 2-year NRM was 23.3%. The 3-year OS and RFS were 58 and 37%, respectively. At least 40% of patients attained a complete molecular response and at least 62% a complete cytogenetic response. In an analysis of 306 CML patients aged 40 years and older undergoing RIC or NMA HCT reported to the CIBMTR from 2001 to 2007, outcomes were similar for patients aged 40–49, 50–59, and over 60 years in terms of the OS at 3 years (54, 52, and 41%, respectively) and treatment-related mortality at 1 year (18, 20, and 13%, respectively). For CP patients, RFS and disease-free survival (DFS) were similar across all ages [23]. These studies indicate that allogeneic RIC HCT is a viable strategy in patients with CML, and that RIC for older CP CML patients treated with TKIs can control relapse with acceptable toxicity and survival.

Donor type

Only approximately one-third of patients have HLA-matched family members to serve as donors. Hence considerable research into the use of alternative donors for transplantation in CML has been conducted. In Chapter 45, details concerning the use of unrelated donors for transplantation in CML are presented. As discussed in that chapter, although early results with matched unrelated donor transplantation in CML suggested results somewhat poorer than seen with matched siblings [24], advances in donor selection, GVHD prophylaxis, and supportive care have resulted in continued improvements in outcome so that now selected single institutions are reporting results almost equivalent to those seen with matched siblings, and registry data are showing 65% survival at 5 years among younger patients transplanted within 1 year of diagnosis [25,26]. In the Seattle experience, survival in CP, AP, and BC are similar between matched-related and unrelated donors (with a caveat that unrelated donor transplants have a lower patient age exclusion). Details about the use of mismatched related donors are presented in Chapter 44, and the use of cord-blood transplants is included in Chapter 39. The experience with autologous transplantation in CML is summarized briefly below.

Source of hematopoietic stem cells

Two separate large randomized trials involving patients with a variety of hematologic malignancies receiving transplants from matched siblings have been published demonstrating that the use of granulocyte-colony-stimulating factor (G-CSF)-mobilized peripheral blood hematopoietic cells, when compared with bone marrow, leads to more rapid myeloid and platelet recovery, no significant difference in acute or chronic GVHD, and an OS advantage. In the studies by Bensinger et al. [27] and Couban et al. [28], there was a trend towards improved survival in CML patients with the use of peripheral blood. A randomized study of CP CML showed no statistically significant differences in outcome between the bone marrow and peripheral blood groups. Relapse rates were lower in the peripheral blood group, but chronic GVHD was higher (and subsequent complications thereof), balancing the survival [29].

Patient age

Initial studies of transplantation for CML in CP from HLA-matched siblings showed that the results deteriorated with increasing patient age. As methods for GVHD prophylaxis and supportive care were improved, the impact of age on outcome appeared to diminish, with no clear effect up to age 65 years using matched related donors, although age seems to be more clearly related to transplant outcome in the unrelated donor setting [9,10,25].

Relapse following transplantation

Graft-versus-leukemia effect in CML

Although evidence for a GVL effect can be found in many settings, nowhere is it as strong as in the setting of allogeneic transplantation for CML. Evidence in support of such an effect includes, first, the higher rates of relapse following syngeneic and T-cell-depleted transplants compared with non-modified allogeneic transplants [30,31]. Second, following non-T-cell-depleted transplants, there is a strong inverse association between acute and chronic GVHD and relapse [32]. Third, response rates to donor lymphocyte infusions to treat post-transplant relapse range from 50 to 100% in various reports, higher than in any other malignancy [33,34]. The markedly increased relapse rates seen with T-cell depletion argue that it is largely a T-cell-mediated process. The targets of T cells might include minor histocompatibility antigens shared by most cells in the body, thus accounting for the association of GVL with GVHD. Alternatively, there may be polymorphic minor histocompatibility antigens with expression limited to hematopoietic tissue. A number of such antigens have been identified [35] and their role as targets for GVL could explain the observation that relapse rates are less following non-T-cell-depleted transplants than with T-cell-depleted transplants even in patients who develop no signs of GVHD. A third possible category of targets for the GVL effect in CML is the over-expression of protein targets in CML cells. T-cell responses could be directed at the tumor-specific peptides spanning the BCR-ABL fusion region, but there is little evidence for the presence of high numbers of T cells with specificity against BCR-ABL in transplant patients. Understanding the cells and their targets responsible for the potent GVL effect seen in CML will be critical to the development of more effective, less toxic transplant-based therapies in the future.

Monitoring minimal residual disease

The fact that CML is always associated with the BCR-ABL translocation coupled with the development of PCR techniques capable of detecting and quantifying extraordinarily small numbers of abnormal cells among a large population of normal ones makes CML an ideal setting to test the capabilities of MRD monitoring to provide insight into the disease and direct therapies. Details about MRD detection are provided in Chapter 25. With non-quantitative PCR techniques, it is possible to detect a single CML cell in a population of 10^5–10^6 cells. Such a qualitative assay was found to be predictive of relapse in 346 patients tested post-transplantation [36]. In over 40% of patients, PCR assays were positive for residual disease at 3 months post-transplant, but this finding was not predictive of outcome, suggesting that eradication of the CML clone post-transplant takes an extended period of time. In contrast, at 6 or 12 months post-transplant, the risk of being PCR positive dropped to ~25%, and here the assay was a powerful predictor of outcome, as 42% of PCR-positive patients subsequently relapsed, compared with 3% of PCR-negative patients ($p < 0.0001$). The predictive power of PCR among long-term survivors is weaker. When studied at 18 months or more post-transplant, only 1% of 289 BCR-ABL-negative patients subsequently relapsed compared with 14% of 90 BCR-ABL-positive patients [37]. The phenomenon of long-lived PCR positivity without relapse has been observed by several groups, and is discussed under “dormancy” in Chapter 25.

The advent of quantitative PCR assays allowed fine tuning of the association of MRD and relapse. Accordingly, attempts have been made to develop quantitative PCR assays and apply them to the post-transplant CML setting. Olavarria et al. [38] studied 138 patients who received allografts, using a quantitative RT-PCR assay performed at 3–5 months post-transplant, and were able to define patients as having a low risk (16%) of relapse, an intermediate risk (43%), or a high risk (86%) based on the quantification of the PCR signal [39]. A more complete discussion of MRD in CML can be found in Chapter 25.

Treatment of post-transplant relapse

The pace of disease progression after post-transplant relapse is variable. Indeed, if relapse is defined at a molecular (PCR) level, some patients may never progress, or at least may not progress for a very long time [37]. Similarly, patients whose only evidence of relapse is detection of low levels of Ph-positive metaphases may remain stable for many years, and even patients with clinical relapse may not progress rapidly. Two retrospective EBMT studies have examined CML patients who relapsed after transplant [40,41]. Stage at transplant and relapse, time from diagnosis to transplantation and from transplantation to relapse, and type of donor (matched sibling vs. volunteer) were all shown to affect survival. Specifically, recipients of matched sibling grafts for CP disease with a short interval from diagnosis to transplant but a long interval from transplant to relapse did particularly well, with a likelihood of being alive at 10 years after post-transplant relapse of 42%. An appreciation of the likely tempo of progression is necessary when considering treatment interventions.

Several potential interventions are available to the patient who has relapsed after allogeneic transplantation for CML. Prior to the introduction of TKIs, treatment with interferon (IFN) was found to produce both clinical and cytogenetic remissions in relapsed patients [42]. More commonly, donor leukocyte infusion (DLI) was used to promote a GVL effect, as detailed in Chapter 70. There have been a large number of studies demonstrating cytogenetic complete response rates of 50–100% in patients treated for clinically relapsed CP CML (reviewed in [43]). Response rates tend to be higher for patients treated earlier at the time of cytogenetic relapse and lower for patients in AP. There is a trend towards improved response rates in patients treated within 2 years after transplantation [44]. The two major complications of DLI are transient marrow failure and the development of GVHD. Most early studies of DLI involved a single infusion of a relatively large number of donor T cells. DLI is better tolerated with less GVHD if administered in a fractionated fashion rather than as a single bulk dose, starting at lower doses of lymphocytes and escalating dosage as required. In a report of 328 patients with relapsed CML who received DLI, 122 (38%) developed some form of GVHD. DLI-related mortality was 11%, disease-related mortality was 20%, and OS for all patients was 69% at 5 years [45].

TKIs have emerged as an initial option for relapsing CML post-transplant [46–52]. As with IFN and DLI, the effectiveness is largely determined by the phase of disease at time of relapse. Responses have been very good in CP patients with high rates (>60%) of both hematologic and cytogenetic remissions [46–49,53]. Fewer studies have evaluated the effect of TKI therapy in patients with advanced disease after HCT, and only a minority of patients achieved a durable remission with TKIs alone [46–48,53]. Post-transplant imatinib treatment is generally well tolerated, with the main toxicity being pancytopenia, which can often be treated with either a temporary discontinuation or dose adjustment. There are limited data with regard to the use of second-generation TKIs for post-transplant relapse [54–57]. The limited data with dasatinib suggest greater toxicity than with imatinib, including gastrointestinal bleeding and pulmonary complications, in addition to the expected hematologic toxicity.

The rationale of combining a TKI with DLI is attractive and has been the focus of a few small studies [50,51]. Although some did not show an improved outcome of combination therapy compared with imatinib alone, one study of 37 patients suggested a beneficial effect of the DLI–imatinib combination compared with the use of either agent alone, as the rates of DFS with DLI–imatinib, imatinib, and DLI were 100, 54, and 43%, respectively.

The optimal time of initiation of TKI therapy after transplant, optimal dose, and duration of TKI therapy for relapsed CML after HCT are unclear. In most post-transplant studies, imatinib at doses of 400–800 mg daily was continued for periods from 9 to 14 months [46–49]. Palandri et al. [58] continued imatinib for longer periods with a median treatment duration of 31 months. In total, 12 of 16 (75%) patients with hematologic, cytogenetic, or molecular relapse of CP or AP/BC achieved molecular CR. This suggests that prolonged treatment with imatinib is effective and feasible in the post-transplant period and can be safely administered over longer periods.

TKIs can be given prophylactically to prevent relapse in high-risk cases [46,59–61].The approach of early TKI therapy, coupled with sensitive molecular monitoring, may allow for prevention or early intervention of disease reoccurrence in CML, and may improve outcomes for transplant in AP disease. However several questions regarding the use of TKIs to treat or prevent relapse post-transplantation remain, including the choice between the use of different TKIs post-transplantation, whether pre-transplant response and BCR-ABL mutations predict for TKI-responsive post-transplantation, and how long treatment needs to be continued after HCT to avoid disease recurrence.

Second transplants have been used to treat patients who have developed recurrent CML following a first transplant. In general, preparative regimens based on chemotherapy only have been used for patients previously exposed to TBI, and TBI-based regimens have been used when the first regimen relied only on chemotherapy. The numbers of second transplants reported in CML are small, yet the data are consistent, reporting regimen-related mortality of ~40%, with long-term DFS of ~25% [62]. As expected, survival in BCs is rare. With the availability of DLI and TKIs, the use of second transplants has diminished substantially.

Autologous transplantation

Experimental and clinical evidence for persistence of polyclonal Ph^- progenitors provided the rationale for autologous transplantation in CML patients [63–65]. Transplantation of autologous Ph^- cells could allow restoration of Ph^- hematopoiesis. Initial studies using unmanipulated autologous marrow or blood cells collected from patients in CP indicated that autologous transplantation could re-establish CP in patients with advanced disease and induce transient cytogenetic responses in a small proportion of patients [66–69]. Subsequent attempts to improve the results of autologous transplantation by ex vivo purging of malignant progenitors from infused cells prior to transplantation showed that ex vivo graft manipulation resulted in depletion of Ph^+ progenitors and was associated with cytogenetic remission post-transplant. However, remissions were of relatively short duration and delayed or partial engraftment was a significant problem. Another approach to depleting malignant cells from the graft was to treat patients with intensive chemotherapy prior to harvesting the autograft (in vivo purging). Autografting of a selected group of CML patients with good cytogenetic responses to intensive treatment was associated with a high incidence of cytogenetic responses post-transplantation [70–72], although other reports were less compelling [73–75]. Moreover, high-dose chemotherapy was often associated with significant toxicity and delayed recovery. An alternative approach to in vivo purging has been to collect PBSCs by growth factor mobilization following induction of cytogenetic responses by IFN-α [76,77] or TKI treatment [78]. The PBSC collection process is feasible and well tolerated. The collection of Ph collections is more consistent than with chemotherapy and IFN-based strategies. However, a subset of patients fail to reach target $CD34^+$ cell collection, and many patients mobilize suboptimally and require multiple collections, possibly as a result of effects of imatinib on normal hematopoiesis and the mobilization process [79]. Collection of PBSCs after a brief discontinuation of imatinib appears to result in greater success. Collections are usually Ph^- by routine cytogenetics and FISH. However, in most patients residual BCR/ABL^+ cells can be detected using sensitive PCR assays. Although the role of autologous HCT has been the subject of a number of studies over more than 25 years, clear evidence of benefit has not been forthcoming. A meta-analysis of six trials in which patients were randomly allocated to receive autologous HCT or an IFN-based regimen did not show an advantage for HCT. Historically, autologous transplant was considered as a treatment option for CML patients without a suitable matched donor. However, in view of the excellent results of imatinib treatment, and the availability of second- and third-generation kinase inhibitors with significant activity in imatinib-resistant CML patients, autologous HCT for CML is not being actively pursued at present.

Awareness of the above factors, along with other contributions of supportive care and GVHD prophylaxis, has made transplantation in CML more successful over time. The pre-transplant prognostic score devised by Gratwohl et al. uses HLA matching, stage, age, gender of donor/recipient, and time from diagnosis to transplant [14]. The scoring system is effective in defining post-transplant outcomes following an ablative transplant, with survival in EBMT data >70% for the best score to <20% for the worst score (Figure 48.2). This scoring was subsequently applied again to EBMT cases transplanted in three cohorts, 1980–1990, 1991–1999, and 2000–2002 [9]. In all risk groups, survival improved over time (overall improvement of >50%), largely from halving of the regimen-related mortality.

However, the dramatic success of TKI therapy has made transplantation a very rare event in CML therapy. Figure 48.3 shows the number of transplants for CML in Seattle and in Europe; the rate descends quickly after the introduction of imatinib in clinical trials, and continues downwards after imatinib achieved regulatory approval in 2001.

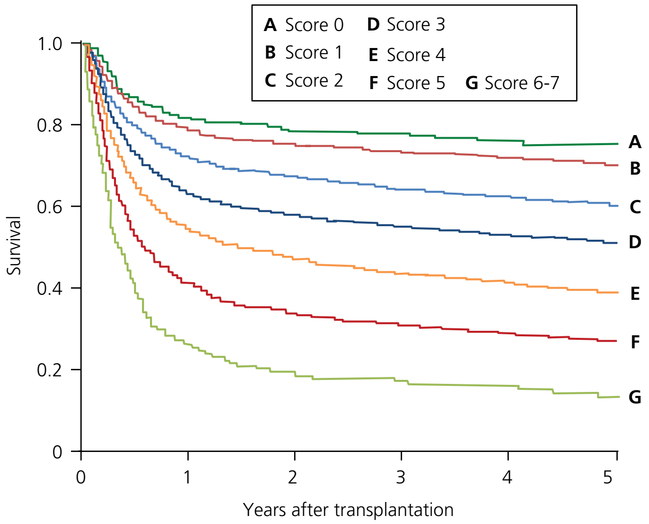

Figure 48.2 Overall survival after allogeneic transplants based on risk assessment score [14]. Components of the score include age, time from diagnosis to transplant, donor type, and donor–host gender.

The Present: TKI therapy and the more limited role of transplantation

The rapid decline of CML transplants reflects the enthusiasm over the clinical success of imatinib (and later, the "second generation TKIs" such as nilotinib and dasatinib). After a decade of TKI use, detailed treatment guidelines have been produced (and constantly updated) by the National Comprehensive Cancer Network (NCCN) (www.nccn.org) and the European Leukemia Network (ELN) (www.leukemia-net.org). Both the NCCN and ELN guidelines are available in print and on the web, and readers are referred there for detailed and current information. However, the highlights of treatment strategies and expected outcomes are outlined below in order to give context to the question of *why and when* transplant should be used in the TKI era.

Front-line TKIs in newly diagnosed CML

The advent of TKIs changed the treatment course in CP CML. To summarize the salient points of TKI therapy: (1) Primary therapy for CP is highly effective, and can produce a complete cytogenetic remission (CCyR) in ~80% of cases. For these patients who achieve CCyR, survival is approximately 90% approaching a decade of follow-up. However, approximately 20–30% of cases will fail primary therapy, from either intolerance, relapse, or progression to advanced phase disease. (2) For patients receiving secondary therapy for resistant disease, approximately 50% will achieve a CCyR. The survival for these patients is ~80% at 3 years. Those who do not response have a relatively short time to progression to advanced phase disease. (3) Patients with AP or BC can respond TKI therapy, but this does not appear to be associated with long-term progression free survival (PFS).

The first approved TKI was imatinib, and much of what we know about response, relapse, and monitoring stems from the large phase III IRIS trial of newly diagnosed CP CML, randomized to imatinib or IFN plus cytarabine. At 12 months, CCyR occurred in ~70% of the imatinib-treated patients versus 7% with IFN–cytarabine therapy. Disease progression was seen in 1.4% of the imatinib group versus 10.3% of the IFN patients. A subsequent 5-year follow-up showed that nearly 70% of imatinib-treated patients remained in complete cytogenetic remission, with an OS of over 85% [80,81].

Two new "second-generation" TKIs have subsequently been approved by the US Food and Drug Administration (FDA) for the treatment of newly diagnosed CP CML. Dasatinib (DAS) is a broad-spectrum kinase inhibitor, which inhibits tyrosine kinases, src kinases, c-KIT, and PDGFR-β, whereas nilotinib (NIL) is a narrow-spectrum TKI, engineered from the structure of imatinib to provide stronger tyrosine kinase inhibition. Phase II and III studies have been remarkably unified in showing that these second-generation TKIs have stronger short-term activity than imatinib (IM) 400 mg/day, including improvements in 12 month CCyR (approximately 80% with NIL or DAS, compared with ~70% with IM) and major molecular response (MMR) rates (~40–50% with the second-generation TKIs vs. 20–30% with IM), higher complete molecular response (CMR) rates, and lower progression to advanced phase disease (1–2% for DAS/NIL vs. 3–4% for IM) (Table 48.2) [82–84]. However, no study has shown a benefit in OS with the second-generation agents compared with IM. It is not clear if this is because there is no difference, or if the benefit is sufficiently small to require greater study numbers, and more follow-up time. At any rate, guidelines by the European Leukemia Network (ELN) and the National Comprehensive Cancer Network (NCCN) both allow for up-front therapy with IM, DAS, and NIL, at the discretion of the physician and patient [85,86].

Table 48.2 12-month responses (%) in ENESTnd [84], DASISION [82], and US Intergroup [83] trials[a]

Response	NIL 300 BID	NIL 400 BID	IM 400	DAS 100	IM 400	DAS 100	IM 400
CCyR	80	78	65	83	72	84	69
MMR	44	43	22	46	28	59	43
AP/BC	0.7	0.4	4.2	1.9	3.5	1	3

CCyR, complete cytogenetic remission; MMR, major molecular response; AP/BC, patients progressing to accelerated phase and blast crisis.

[a] Doses in mg/day unless indicated otherwise.

Second-line TKI therapy after imatinib failure or intolerance

Resistance to imatinib can be either primary (intrinsic), where patients fail to respond to treatment, or secondary (acquired), where resistance develops after an initial response [87]. In the IRIS trial, an estimated 16% of patients with newly diagnosed CP CML failed to achieve a major cytogenetic response (MCyR) after 12 months of imatinib and approximately 24% failed to achieve a CCyR after 18 months of imatinib therapy. Acquired resistance was also observed in 17% of cases, with 7% of patients progressing to AP or BC CML [80].

Primary resistance to imatinib may involve BCR-ABL-independent mechanisms, such as alterations in drug transporter influx (Oct-1) and efflux (ABC proteins), or other signaling pathways besides BCR-ABL, such as the SRC-family kinases (SFKs), which are substrates and downstream mediators of BCR-ABL signaling [88–91]. Several mechanisms underlie "acquired" (secondary) imatinib resistance, including amplification of the Ph, and the acquisition of point mutations in the ABL kinase domain (KD) of the BCR-ABL fusion protein [92,93]. BCR-ABL mutations are the most common cause of imatinib resistance (40–90%) and inhibit imatinib binding and efficacy by either inducing a structural change towards the active conformation of the protein, causing a shift in the equilibrium of BCR-ABL from inactive (which imatinib binds) to active (which imatinib is unable to bind), or by mutating critical binding sites in the molecule. More than 100 different BCR-ABL KD mutations have been found [94]. The likelihood of acquiring a BCR-ABL KD mutation increases with the phase of disease and length of time from diagnosis to treatment. Thus, the acquisition of KD mutations increases with advanced phase disease and in CP patients with a longer time (>1 year) from diagnosis to initiating imatinib therapy [95].

Four TKIs (nilotinib, dasatinib, ponatinib, and bosutinib) are now available and are recommended for the treatment of patients who are intolerant or resistant to imatinib [85,86]. In addition, the cetaxine from the Chinese plum yew tree, omacetaxine (formerly homoharringtonine), has shown modest activity in cases that have failed multiple TKIs. All the TKIs have a remarkably similar response in imatinib-intolerant and -resistant cases, producing CCyR in ~70% of cases of imatinib intolerance and 40–50% CCyR in cases treated for resistance [96,97]. The choice of which TKI to use as second-line therapy is based on several factors, including (a) existing comorbidities (e.g., cardiac risks in nilotinib, pulmonary with dasatinib), and (b) the specific BCR-ABL KD mutation. Each of these TKIs has a different spectrum of activity to different point mutations, as determined by in vitro drug inhibitory assays. Of note is that of the approved TKIs, only ponatinib has activity against the T315I "gatekeeper" mutation. The last important factor in TKI selection is the physician's familiarity with use. Since CML is a rare disease, physicians often have more comfort with one TKI than another; if there is no clear drug preference based on comorbidity or mutation, experience is an important factor in TKI choice.

Before the introduction of second-line TKIs, imatinib resistance was associated with a relatively rapid progression to advanced phase disease, especially with mutations the P-loop region of ABL [98–100]. The 3-year survival rate for imatinib-resistant patients with CP CML was 72%, falling to 30% for patients with AP CML and 7% for BC CML [99]. Second-generation TKIs have activity in advanced disease; for example, 27 and 43% of myeloid and lymphoid BC, respectively, achieved a CCyR on dasatinib therapy as a single agent. Unfortunately, the response was short-lived, as the median PFS was 5 and 3 months for myeloid and lymphoid BC, respectively [101,102].

Monitoring disease response to TKIs

Several layers of monitoring can be used CML, each associated with a level of disease response, and linked to treatment guidelines of the ELN and NCCN. *Complete hematologic response* (CHR) refers to the normalization of peripheral blood counts. In CP CML, all of the TKIs are associated with a >90% CHR rate by 3 months of therapy, and failure to achieve such a response is considered an indicator of a treatment failure. *Cytogenetic response* refers to the number of Ph chromosome metaphases among at least 20 metaphase preparations, and is the strongest prognostic factor for predicting long-term response to TKIs once patients have achieved a CHR. Achieving a CCyR is an independent prognostic factor for survival, and is the next major a goal of therapy after CHR. Failure to achieve any reduction in the number of Ph+ cells after 6 months of imatinib therapy and failure to achieve an MCyR response after 12 months of imatinib therapy predicts a <20% chance of ever achieving a CCyR [103]. Additionally, studies have shown that achieving an MCyR at 3 months is associated with prolonged time to disease progression in patients with late CP and AP CML [104,105]. FISH (see Chapter 25) has a somewhat limited role in BCR-ABL monitoring. At diagnosis, it should not replace conventional cytogenetics, since it cannot detect other chromosomal changes indicative of AP disease. It can, however, be used in the diagnostic setting if the patient has an inaspirable bone marrow. FISH is not adequately sensitive for following low levels of residual disease once a patient has achieved a CCyR. To study disease levels below that detectable by cytogenetics, *molecular response* using quantitative RT-PCR (see Chapter 25) of the chimeric BCR-ABL mRNA transcript is the most sensitive method to monitor disease burden, and can be combined with cytogenetics to predict outcome. Results from the IRIS trial showed that patients who had achieved a CCyR after 12 months of imatinib had a significantly lower risk of disease progression than patients without a CCyR. Patients who had both a CCyR and "major molecular response" (or MMR, a >3 log reduction of BCR-ABL transcript level from an aggregate baseline of 30 newly diagnosed patients) at 12 months of imatinib therapy had a 100% probability of remaining progression free at 24 months. In comparison, patients with a CCyR and <3 log reduction of BCR-ABL had 95% PFS, and patients who did not achieve a CCyR by 12 months had an 86% PFS [106]. Five-year follow-up data from this study revealed that no patient who achieved an MMR by 12 months had progressed to advanced disease [80].

Earlier responses after 3–6 months of TKI therapy may also be a predictor of long-term outcome. Several studies have shown that both OS and PFS are improved in patients who achieve a cytogenetic response at 3 or 6 months [105,107]. In addition, early molecular responses have also been shown to be associated with better outcome, as those patients who fail to achieve a 1–2 log reduction after 3 months of therapy are less likely to ever achieve an MMR [108–110]. In a large study of CP cases, it was shown that the achievement of an MMR at 3, 6, and 12 months was highly correlated with the duration of a CCyR. For example, for those patients who achieved a CCyR after 3 months of therapy, the subset who also achieved an MMR at that time had a 0% risk of relapse in the next 2 years, compared with a 20% risk for those without an MMR. This trend also held true for those in a CCyR at 6 and 12 months [109]. The significance of a poor response at 3 months appears strongest for those patients who fail to achieve a reduction in BCR-ABL to <10% International Scale (IS); this association of poor initial response and CCyR, OS, and EFS is evident in patients treated with both low- and high-dose imatinib, dasatinib, or nilotinib [111–113]. For example, a large study of 483 newly diagnosed CP cases showed that the EFS for cases with a BCR-ABL <10% at 3 months was 61%, compared with >95% in cases with a superior molecular response [114].

Both the ELN and the NCCN have published guidelines with respect to patient monitoring, treatment milestones, and therapeutic options. Thankfully, the recommendations are fairly similar. For example, the NCCN sets treatment goals as the achievement of a complete hematologic remission and a minor cytogentic response and/or the achievement of a BCR-ABL transcript value of <10% IS by 3 months, and a complete cytogenetic response by 12 months. The recommended monitoring schedule is based on the above treatment milestones. Thus in the NCCN guidelines, cytogenetic testing of bone marrow is recommended diagnosis, and at 3 and 12 months after the start of therapy. PCR testing for BCR-ABL begins at diagnosis and continues at 3-month intervals. Once a CCyR has been achieved, monitoring continues by peripheral blood BCR-ABL PCR testing alone.

Peripheral blood BCR-ABL is used both to access the degree of response, and also to detect early resistance. A rise in BCR-ABL is considered significant if BCR-ABL increases 5–10-fold on repeat measurements 1 month apart. If this occurs, this should trigger (a) inquiries about adherence to therapy (which is remarkably and surprisingly poor with TKI) [115,116], and (b) mutation studies of BCR-ABL.

As noted above, the detection of specific ABL point mutations can inform which other TKIs should be used as second-line therapy, based on in vitro drug inhibition studies [117]. The most common clinically significant mutations, and the appropriate drug choice, are shown in Table 48.3. Note that ponatinib appears to have activity for all ABL mutations so far detected. Resistance in the absence of a BCR-ABL KD mutation may be significant, since it suggests that resistance is occurring through a mechanism not dependent on BCR-ABL signaling (since in the absence of a mutation, it should be inhibited by the TKI).

Table 48.3 Options for specific BCR-ABL tyrosine kinase domain mutations[a]

Mutation	Treatment options
T315I	Ponatinib, HCT, omacetaxine, clinical trial
V299L	Nilotinib, ponatinib, omacetaxine
T315A	Nilotinib, ponatinib, imatinib, bosutinib, omacetaxine
F317L/V/I/C	Nilotinib, ponatinib, bosutinib, omacetaxine
Y253H, E255K/V, F359V/C/I	Dasatinib, ponatinib, bosutinib, omacetaxine

[a] As discussed in the text, preferences are based on the activity of the TKI versus the specific agent, patient comorbidities, and familiarity of the medication to the prescribing physician. A special exception is the T315I mutation, where the only available TKI with activity is ponatinib.

Who and when do we transplant?

Given the above summary of the TKI treatment experience, and the contemporary results of transplant, can we develop general "rules of engagement" for to whom and when we should offer transplantation? While this strategy is evolving, we can ask and answer some basic questions that can clarify our treatment course.

Should we ever offer transplantation as a first option?

Given the great results of front-line imatinib in newly diagnosed CP CML, the situations where transplantation should be offered first seem few. However, in health systems where a TKI cannot be obtained (owing to financial limitations or other bureaucratic/infrastructure restrictions), then transplant would be a good option for initial therapy of CP disease [118].

Very few CML cases present with advanced phase disease. It is important to remember that although CML is categorized in three phases, in reality the disease is a continuum, hence it is not sensible to consider an AP case with 19% blasts differently from a BCs case with 20% blasts. For BC patients, initial therapy with a TKI is warranted as a "bridge" to transplantation, which should be performed as expeditiously as possible. There is not as clear a consensus for patients presenting with AP disease, partly because of the wide variety of definitions of that clinical state. It is reasonable to start all newly diagnosed AP patients on a TKI, with a quick consultation with the transplant team. Patients with AP disease only by cytogenetic criteria (i.e., low blast counts and another cytogenetic abnormality besides the Ph) may be observed to see if they "behave" like a CP patient (since many of the TKI trials categorized these cases as CP), whereas AP patients who look more like BC cases (high blast count, large spleen, etc.) should be transplanted sooner rather than later.

When should transplantation be used after initial TKI failure?

There is increasing evidence that resistance may last forever. Fewer than 50% of cases of IM failure achieve a CCyR with secondary TKI therapy [101,119]. Moreover, patients who do fail secondary therapy often have a new mutation [120–122]. Hence secondary TKI therapy may be an unfortunate example of the Darwinian selection of fit clones that survive each successive therapeutic attack. Moreover, molecular data have shown than the biological states of resistance and progression have a large overlap [123–125]. Given these facts, it is reasonable to prepare patients for transplantation at the time of first-line failure. This means a consultation at a transplant center, and lining up a donor, either sibling or unrelated.

It is certainly reasonable, and sensible, to start a secondary TKI at the time of resistance, for two reasons: first, in case the patient is one of the fortunate ones who obtain a CCyR on secondary therapy; and second, a donor search can take months (especially for an unrelated donor), so therapy is needed to blunt the progression of the disease. Efforts have been made to identify clinical or laboratory variables that will predict outcome after the initiation of secondary TKI therapy. At present, patients with early cytogenetic response to a secondary TKI seem to do well. Thus, patients who are placed on a secondary TKI, but who fail to have any cytogenetic response after 3 months of therapy, are very unlikely ever to achieve a CCyR. Likewise, failure to achieve at least a minor cytogenetic response by 6 months, or an MCyR by 12 months of secondary therapy, bodes poorly for sustained disease control [126]. A scoring system based on the best cytogenetic score on imatinib therapy, Sokal score, and a history of neutropenia during imatinib therapy has been proposed by the Hammersmith group. Patients with a low score (few adverse features) had a >90% chance of achieving a CCyR on a secondary agent, compared with <20% for cases with a high score (several adverse features) [126,127].

There are a few special circumstances where a move to transplant is warranted after front-line TKI failure. If a patient has relapsed with a T315I mutation, ponatinib can be used if available (it is not approved in all countries as of this printing, but if ponatinib is not available, then transplantation should be offered once a donor has been secured. In addition, patients who progress to advanced phase disease while on a TKI have a very poor prognosis (median survival 10 months), and these patients should be moved to transplant as soon as possible. If mutation analysis points to the use of a particular TKI, it can be used as a bridge to transplant.

As noted above, patients who have a particularly poor response after 3 months of therapy have a comparatively poor PFS. While the NCCN suggests that these patients switch their TKI, it is not known if that will change the outcome for these patients. Therefore, they may benefit from a transplant discussion, initiation of HLA typing, and perhaps more frequent molecular monitoring once the switch to the new TKI has been made.

It is very unusual for patients to be intolerant of all the available TKIs, although it does rarely occur. If patients cannot be adequately dosed with a TKI, owing to either hematologic or non-hematologic toxicity, then transplantation should be considered.

Does prior treatment with TKIs affect transplant results?

There have been several studies on the effect of prior imatinib and transplant outcomes. Early reports warned of an increase in regimen-related toxicity and mortality, especially from hepatic causes [128]. Larger studies have failed to show a deleterious effect of pre-transplant imatinib [129,130]. A study of 140 CML patients showed no difference in regimen-related mortality, survival, or relapse in patients who received imatinib versus 200 historical controls [131]. Indeed, an IBMTR study of 409 patients who received imatinib therapy transplant compared with 900 patients who did not suggested that those CP patients who received imatinib enjoyed a slightly better outcome following transplant, although this effect seemed to be limited in cases who moved to transplantation because they could not tolerate imatinib, rather than treatment failure [132]. There was no positive or negative effect of imatinib on the outcome for advanced phase patients. So far, there is no evidence that resistant patients with Abl mutations have a poorer outcome following transplantation.

In a study of imatinib-resistant CML patients who underwent HCT and had BCR-ABL mutation analysis, 32 of 47 transplanted patients (68%) had at least a major molecular response. The 2-year EFS was 36 and 58% and OS was 44 and 76%, for patients with or without BCR-ABL mutations, respectively [133]. Recent results suggest that HCT is an effective strategy for patients with CML who have the T315I mutation [134]. Results for 84 patients who underwent transplantation in the randomized German CML Study IV according to predefined criteria (low EBMT score, imatinib failure, and advanced disease), showed that 3-year survival of 56 CP patients at 30 months was 91%, and of 28 AP patients 59%. The complete molecular remission rate after HCT was 88% [11]. These results suggest that HCT is an important salvage option for TKI-resistant patients with or without BCR-ABL mutations, including the T315I mutation, particularly in earlier stages.

The future of CML treatment

CML serves as an excellent model for how insights into the molecular basis of a malignant disease can be translated into powerful diagnostic tools and highly effective therapies. We now have a near "embarrassment of riches" with regard to effective treatment options, but there are still questions that point to future improvements of care:

1. Can we predict the "bad actors" prior to therapy, and pick the right agent for the job? Efforts to achieve this by clinical and genomic methods have been mixed. The reason for the uneven success is unclear, but may be largely due to the poor adherence of TKI therapy, as patients may do not respond because they are poorly compliant but have a responder genotype, who may be misclassified. However, one hopes that pretreatment prediction, added to an early kinetic assessment by PCR, might quickly suggest which patients need a more aggressive approach than a TKI alone.
2. Will early switching after 3–6 months of ineffective therapy improve outcomes? It is hoped that trials will quickly enlighten us. Although it is optimistic to think that switching to another TKI will help, it may well be that these cases have a biology that will require something more – transplantation, perhaps, or combination therapy in the context of a clinical trial.
3. Will patients be "cured" with TKIs? There has recently been great interest in discontinuing TKI treatment in patients with a prolonged CMR. It appears that roughly 40% of patients with prolonged TKI exposure may reach sustained CMR; once TKI treatment is stopped, roughly 40% will remain in CMR off TKIs. Thus, a "functional cure" may be achievable in 0.40 × 0.40 = 16% of CML cases. How will we make this better? One might imagine the use of combination therapies, particularly immunologic approaches, to push patients from the MMR range of disease burden into CMR. Indeed, once the community demands drug-free molecular negativity, transplant popularity may increase, as one can imagine potent TKI therapy followed by an NMA regimen as a strong combined approach in select cases.

CHAPTER 49

Hematopoietic Cell Transplantation for Juvenile Myelomonocytic Leukemia

Charlotte M. Niemeyer[1] **and Franco Locatelli**[2]
[1] University of Freiburg, Freiburg im Breisgau, Germany
[2] University of Pavia, Pavia, and Ospedale Pediatrico Bambino Gesù, Rome, Italy

Introduction

Heterogeneity in presentation has long impaired a rational approach to the clinical management of children with juvenile myelomonocytic leukemia (JMML). The recent discovery that approximately 90% of children with JMML have either somatic or germline mutations in genes involved in the RAS signal transduction pathway, such as *PTPN11* (the gene encoding SHP-2), *CBL*, *NRAS*, *KRAS*, or *NF1*, has greatly improved our understanding of the molecular pathogenesis of this disorder. Further, it enormously facilitated diagnosis by allowing mutational analyses. With clinical diagnosis confirmed by molecular markers, allogeneic hematopoietic cell transplantation (HCT) can be performed early in the course of the disease. In addition, monitoring of minimal residual disease following transplantation has become feasible for many cases. This chapter summarizes the clinical and molecular features of JMML and reviews the role of HCT.

Classification and epidemiology

JMML is a clonal hematopoietic disorder of early childhood characterized by excessive proliferation of monocytic and granulocytic cells. Following a first case description in 1924 [1], Jean Bernard and his co-workers in Paris carefully described the clinical picture in a group of 20 children in 1962 [2]. They referred to the disorder as subacute and chronic myelomonocytic leukemia and identified prognostic factors for survival [3]. Following the demonstration that the Philadelphia chromosome was absent in infants with chronic myelomonocytic leukemia, Hardisty et al. coined the term “juvenile CML” (jCML) [4], and it became common practice to contrast JMML with Philadelphia chromosome-positive chronic myelogenous leukemia (CML) [5]. At the same time, British colleagues proposed a separate entity in children with myeloproliferative disorders and monosomy 7. This infantile monosomy 7 syndrome had clinical features similar to those of jCML, but low hemoglobin F (HbF) levels [6]. Meanwhile, the French–American–British (FAB) group had rationalized the morphologic classification of myelodysplastic syndrome (MDS) in adults [7]. Some investigators argued for the application of modified FAB criteria in children and used the term chronic myelomonocytic leukemia (CMML) instead of jCML [8]. To avoid further confusion, in 1996, an international working group under the direction of Robert Castleberry proposed the term juvenile myelomonocytic leukemia (JMML) and established criteria for confirming diagnosis [9]. JMML incorporates those disorders previously referred to as jCML or CMML of infancy, and also some cases of the infantile monosomy 7 syndrome [10]. To account for both the myelodysplastic and proliferative features noted in JMML, the WHO classification placed the entity in the group of myelodysplastic/myeloproliferative disorders [11,12].

JMML accounts for about 2–3% of all childhood hematologic malignancies [13]. Incidence studies from Denmark and British Columbia showed a JMML incidence of 1.2 per million children per year [13], while a much lower incidence of 0.6 per million has been reported from the United Kingdom [14]. It is unknown whether these differences are due to different geographic incidence rates or to variations in reporting.

Clinical presentation and differential diagnosis

JMML predominates in infants with a median age at diagnosis of 2 years [3,8]. About 9% of patients are diagnosed by the age of 4 months, whereas only 8% are 6 years or older. There is a male predominance, with a male-to-female ratio of 2:1.

Pallor, fever, infection, skin bleeding, and cough are the most commonly presenting symptoms [8]. Marked splenomegaly and hepatomegaly are generally present and may give rise to abdominal discomfort. Occasionally, spleen size is normal at diagnosis, but it rapidly increases thereafter. Gut infiltrates may predispose to diarrhea, sometimes with bloody features, and gastrointestinal infections. About half the patients have lymphadenopathy [8,15]. In addition, leukemic infiltrates may give rise to markedly enlarged tonsils. Dry cough, tachypnea, and interstitial infiltrates on chest X-ray are signs of peribronchial and interstitial pulmonary infiltrates. JMML rarely involves the central nervous system, although a small number of patients with local leukemic infiltration and ocular chloroma, diabetes insipidus, or facial palsy have been described [8].

Leukemic skin infiltrates are common. Most often they present as eczematous eruptions or indurated raised lesions with a central clearing. In addition to these often non-specific lesions, juvenile xanthogranulomas may be seen. In some children, xanthogranulomas are associated with multiple café au lait spots and the clinical diagnosis of neurofibromatosis type 1 (NF1); in children with

germline CBL syndrome, a Noonan syndrome (NS)-like phenotype, one or two café au lait spots may be present [16].

Signs of autoimmunity such as antinuclear antibodies or positive antiglobin test can be noted in up 25% of children with JMML, while hypergammaglobulinemia is present in more than half of them [8]. In occasional cases with RAS mutations, autoimmunity, and indolent clinical course, the diagnosis of autoimmune lymphoproliferative syndrome (ALPS) has been entertained [17,18]. Although ALPS is generally characterized by a sustained elevation of αβ double negative T cells and leukopenia rather than myeloproliferation, there might be overlap cases.

The clinical picture of JMML can be mimicked by a number of viral infections, such as Epstein–Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus-6 (HHV-6), or severe bacterial disease, such as endocarditis [19–21]. More interestingly, some children with leukocyte adhesion deficiency [21], infantile malignant osteopetrosis [21], or Wiskott–Aldrich syndrome (WAS) [22] can present with a picture morphologically and clinically resembling JMML. Hence the latter disorders need to be excluded in infants with myeloproliferation in the absence of a molecular lesion of the RAS signal transduction pathway. Myeloproliferation with monosomy 7 but absence of splenomegaly can be noted in rare cases of GATA2-haploinsufficiency syndrome [23]. In some JMML cases, striking hemophagocytosis is observed; although hemophagocytic lymphohistiocytosis (HLH) is characterized by a low rather than elevated white blood cell (WBC) count, the differential diagnosis between these two rare disorders can be puzzling [24].

JMML in neurofibromatosis type 1

The diagnosis of NF1 with multiple café au lait spots can be established in up to 11% of children with JMML [3,6]. As estimated from these data, the risk of developing JMML for patients with NF1 is 200–350-fold higher than in patients without NF1 [25]. A positive family history for NF1 is known in about half of cases of NF1 and JMML. Although clinical parameters generally do not differ between patients with or without NF1, NF1 is more common among the few patients who are diagnosed after the age of 5 years. In addition, children with NF1 have a higher platelet count and higher percentage of blasts in the bone marrow (BM) than patients without NF1 [8].

Myeloproliferation and JMML in Noonan syndrome and related rasopathies

Germline mutations in a number of genes coding components of the RAS-MAP kinase-signaling pathway have led to the definition of a new group of autosomal dominant, genetic disorders, the so-called neuro-cardio-facio-cutaneous syndromes or RASopathies [26]. They comprise NF1 (see above), Noonan syndrome (NS), and NS-related disorders. NS is characterized by short stature, distinct facial anomalies, a typical spectrum of congenital heart defects, including stenosis of the pulmonary artery, hypertrophic cardiomyopathy, and septal defects, mild coagulopathy, and often developmental delay, in addition to failure to thrive. Approximately 50% of patients with NS have germline mutations in the *PTPN11* gene encoding for SHP-2, a tyrosine phosphatase protein [27].

Some infants with NS develop a myeloproliferative disorder within the first months of life that is clinically and hematologically indistinguishable from JMML [28]. On a molecular level, these children harbor germline *PTPN11* mutations, which exhibit a weaker "gain of function" effect of the phosphatase SHP-2 than the acquired somatic mutants found in JMML [29,30] (see the later section Molecular pathogenesis). Most children with NS and a myeloproliferative disorder show spontaneous resolution of their myeloproliferation [28]. They are, however, often critically ill and may benefit from intermittent cytoreductive therapy, for example, with 6-mercaptopurine [31]. Few patients with NS and myeloproliferation acquire additional lesions such as cytogenetic aberrations and thus experience an aggressive clinical course [28].

In rare cases, NS can be caused by constitutional *KRAS* [32] or *NRAS* mutations [33], and some of these patients may present with a myeloproliferative disorder resembling JMML [32,34,35].

Another less common rasopathy with NS-like clinical features is caused by constitutional mutations in *CBL* which functions as an E3 ubiquitin ligase [16]. Interestingly, children with CBL syndrome and JMML may show 1–2 café au lait spots and xanthogranuloma [16].

Hematologic features

Leukocytosis, thrombocytopenia, and anemia are common findings in JMML patients. The median WBC count is 33×10^9/L [3,8,15]. In contrast to Philadelphia-positive CML, the WBC count rarely exceeds 100×10^9/L. A presenting WBC count under 10×10^9/L is occasionally noted, particularly in children with monosomy 7 [6,8].

Microscopy of the peripheral blood smear is the most important step in establishing the diagnosis. Immature monocytes, along with myelocytes, metamyelocytes, and nucleated red blood cells, are usually evident. Almost all cases show a striking monocytosis, often with dysplastic cell forms, and an absolute monocyte count exceeding 1×10^9/L is required for the diagnosis of JMML (Table 49.1) [9]. Often, a few blasts can be noted on peripheral blood smears, but they rarely exceed 20% [8]. Thrombocytopenia is a common finding, with about 14% of children having a platelet count at diagnosis below 20×10^9/L. Most patients have a hemoglobin concentration between 7 and 11 g per 100 mL. Red blood cells are generally normocytic, while macrocytosis is noted in some patients with monosomy 7 [8].

BM findings in JMML are not by themselves diagnostic, but rather are consistent with the diagnosis. The aspirate shows a high cell number with predominance of granulocytic cells at all stages of

Table 49.1 Diagnostic criteria of JMML

I. Clinical and hematological features (all three features mandatory)
  - Peripheral blood monocyte count $>1 \times 10^9$/L
  - Blast percentage in peripheral blood and BM <20%
  - Splenomegaly

II. Oncogenetic studies (1 sufficient)
  - Somatic mutation in *PTPN11*[a] or *KRAS*[a] or *NRAS*[a,b]
  - Clinical diagnosis of NF1 or germline *NF1* mutation
  - Germline *CBL* mutation and loss of heterozygosity of *CBL*[c]

III. In the absence of one parameter listed under II, the following criteria have to be fulfilled:
  - Absence of Philadelphia chromosome (*BCR/ABL* rearrangement)
  - Absence of GATA-2 germline mutation
  - And at least two of the following criteria:
    - Spontaneous growth or GM-CSF hypersensitivity in colony assay
    - Hemoglobin F increased for age
    - Myeloid precursors on peripheral blood smear
    - White blood cell count $>10 \times 10^9$/L
    - Monosomy 7 or other chromosomal abnormality

---

[a] Germline mutations (indicating Noonan syndrome) need to be excluded.

Diagnosis of JMML but spontaneous regression of myeloproliferation may be noted in:

[b] Very few patients with NRAS mutation and normal HbF.

[c] Patients with *CBL* germline mutation and loss of heterozygosity.

Source: adapted from Gratwohl et al. 2009 [9].

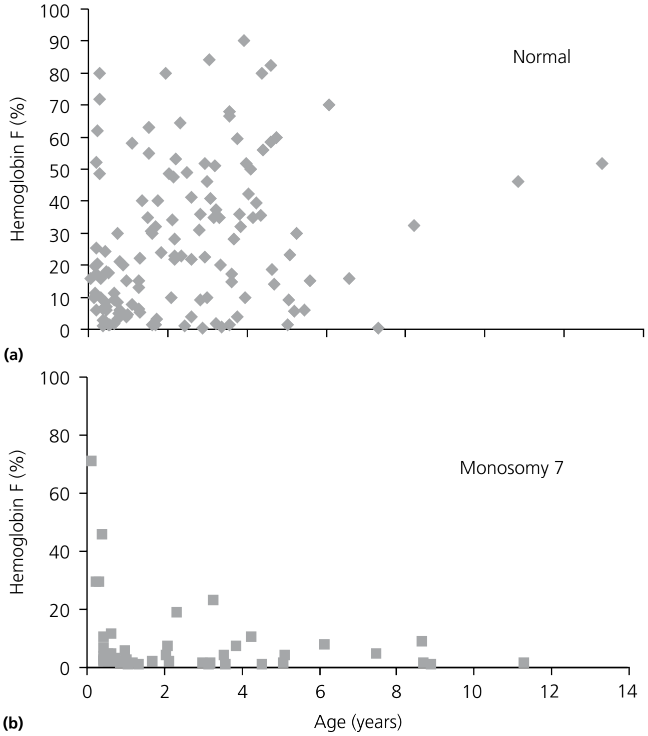

Figure 49.1 Concentration of hemoglobin F for patients with JMML and either normal karyotype (a) or monosomy 7 (b).

maturation, except for the few cases in which the erythroid series predominates. Monocytosis in BM is generally less impressive than that in peripheral blood [3,8]. The marrow blast count is moderately elevated, but never reaches the level seen in acute leukemia. Megakaryocytes are reduced in number or absent in about two-thirds of cases. A remarkable feature of many JMML cases with a normal karyotype is a markedly increased synthesis of HbF (Figure 49.1), resulting from a high number of circulating F cells [36].

Chromosomal abnormalities

Chromosomal studies of leukemic cells show monosomy 7 in approximately 25% of JMML patients, with other abnormalities in 10%, but the majority (65%) have a normal karyotype [6,8,15]. Although the clinical characteristics of patients with monosomy 7 do not differ from those of patients with a normal karyotype, patients with monosomy 7 display some characteristic hematologic features [8]. In addition to a lower median WBC count, red blood cells are often macrocytic, and erythropoiesis in BM is more pronounced than in cases with a normal karyotype. In addition, patients with monosomy 7 present with a normal or only moderately elevated HbF, which is often elevated in patients with normal karyotype (Figure 49.1). Among the chromosomal abnormalities other than monosomy 7, loss of material on the long arm of chromosome 7 is frequent [8]. As mentioned before, JMML lacks the Philadelphia chromosome and the *BCR-ABL* fusion gene.

Molecular pathogenesis

A hallmark feature of JMML is the formation of abnormally high numbers of granulocyte–macrophage colony-forming units (CFU-GM) in methylcellulose cultures containing low concentrations of granulocyte-macrophage colony-stimulating factor (GM-CSF) [37]. Thus, GM-CSF hypersensitivity of myeloid progenitors had been utilized as an important diagnostic tool. Phosphorylation of the βc chain of the GM-CSF receptor creates docking sites for adapters and signal relay molecules, resulting in activation of the RAS pathway.

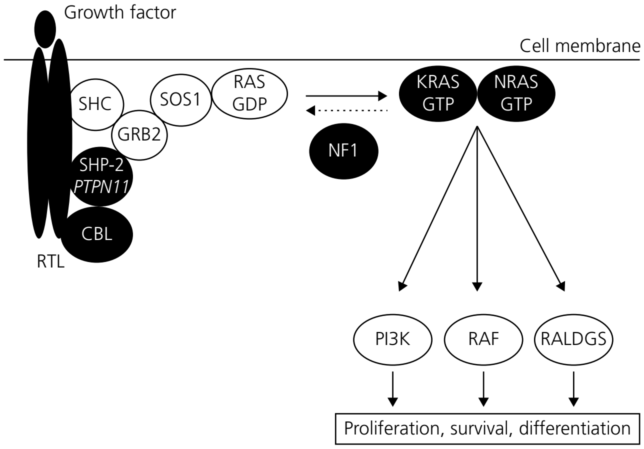

Figure 49.2 Simplified RAS signaling pathway. Proteins involved in the pathogenesis of JMML (due to biallelic inactivation of *NF1*, *CBL*, or heterozygous somatic mutations in *PTPN11*, *KRAS*, or *NRAS*) are indicated in black.

Studies on human leukemic cells and mouse models provided evidence that GM-CSF hypersensitivity is due to a selective inability to downregulate RAS-dependent signaling pathways (Figure 49.2). In 90% of JMML cases, the pathologic inactivation of the RAS signaling cascade results from oncogenic molecular alterations in *NF1*, *PTPN11*, *NRAS*, *KRAS*, or *CBL*. Downstream of RAS, the activation of the Raf/MEK/ERK pathway, the phosphoinositide-3 kinase (PI3K)/Akt/mTOR cascade, and RALGDS are implicated in malignant transformation and tumor maintenance [38] (Figure 49.1).

Dominant somatic mutations of *KRAS* and *NRAS*

Approximately 25% of JMML cases harbor dominant somatic mutations of *NRAS* or *KRAS* in hematopoietic cells [39,40]. Members of the RAS family of signaling proteins regulate cellular proliferation by cycling between an active guanosine triphosphate (GTP)-bound state (RAS-GTP) and an inactive guanosine diphosphate (GDP)-bound state (RAS-GDP). Highly conserved regions within RAS that are crucial for the function of RAS as a molecular switch include the phosphate-binding (P) loop (codons 11–16) and the switch I (codons 33–37), and switch II (codons 59–66) regions [41]. Oncogenic *RAS* mutations typically introduce amino acid substitutions at positions Gly12, Gly13, or Gln61. Mutant *RAS* alleles encode proteins that are locked in the GTP-bound conformation.

Expressing oncogenic *KRAS*^{G12D} is sufficient to initiate a rapidly fatal myeloproliferative disorder in mice associated with hyperproliferation, tissue infiltration, and aberrant responses to growth factors [42,43]. While the myeloproliferative disorder initiating activity is restricted to hematopoietic stem cells that acquire a competitive proliferative advantage over wild-type cells [44], cooperation with additional genetic events is needed to produce frank malignancy [45]. Children with JMML and somatic *KRAS* mutations generally have a fatal clinical course [39], although Japanese investigators reported some cases with long-term spontaneous improvements

[46,47]. Uniparenteral disomy of *KRAS* can contribute to aggressive leukemic transformation [48].

Mouse models demonstrate clear phenotypic differences between mutant KRAS and NRAS [38,49]. Expressing *NRAS*^{G12D} from its endogenous genetic locus produces an indolent myeloproliferative disorder in mice, which ultimately die of a diverse spectrum of hematologic cancers [50]. Similarly, in an HSCT model harboring the *NRAS*^{G12D} mutation, recipient mice develop myeloproliferative disease with a prolonged latency and acquisition of multiple genetic alterations, including uniparental disomy of the oncogenic *NRAS* allele [51]. Children with JMML and somatic *NRAS* mutations generally have a fatal course unless HCT is performed. However, in a small number of infants with *NRAS* alterations and normal HbF spontaneous resolution of myeloproliferation despite persistence of the *NRAS* mutated clone, and long-term survival in the absence of HCT was been observed [52].

Germline mutations in *NF1* and loss of heterozygosity

The conversion from active RAS-GTP to the inactive RAS-GDP state is facilitated by GTPase-activating proteins (GAPs). Neurofibromin, the protein encoded by the gene for NF1, functions as a GAP and negatively regulates *RAS*. As described above, 11% of children with JMML have constitutional NF1 [3]. These patients carry one intact and one deficient allele of the *NF1* tumor suppressor gene in the germline. Loss of the normal *NF1* allele is common in JMML cells from children with NF1, resulting in severely deregulated RAS signaling with aberrant growth of hematopoietic progenitor colonies in vitro. Two studies indicated that a common mechanism of NF1 inactivation is loss of heterozygosity based on uniparental disomy (UPD) replacing the wild-type *NF1* allele by the second copy bearing the *NF1* mutation [53,54]. In a mouse model, some heterozygous *Nf1* mutant animals develop a myeloproliferative disorder [55] and recipient mice reconstituted with *Nf1*$^{-/-}$ fetal hematopoietic cells succumb to a rapidly fatal disease that models JMML [56].

Dominant somatic mutations in *PTPN11*

Shortly after the discovery of mutations in protein tyrosine phosphatase non-receptor type 11 (*PTPN11*) in about 50% of patients with NS, specific germline *PTPN11* alterations were identified in the young children with NS syndrome who developed a myeloproliferative disorder within the first few weeks of life [29,57]. Subsequently, somatic *PTPN11* mutations were uncovered in JMML cells from 35% of children with JMML [29,57]. The *PTPN11* gene encodes for SHP-2, a tyrosine phosphatase protein that relays growth signals from activated growth factor receptors to other signaling molecules, including RAS. Most *PTPN11* mutations are predicted to disrupt the autoinhibition of the catalytic protein tyrosine phosphatase (PTPase) domain by the N-terminal src-homology 2 (N-SH2) domain, thereby promoting the active conformation of the protein [58]. Somatic mutations observed in patients with JMML differ from those mutations found in patients with NS and JMML-like myeloproliferation and from those detected in patients with NS alone [30]. In elegant functional experiments, several groups have shown that somatic *PTPN11* mutations associated with sporadic JMML exhibit stronger biochemical and biological effects than germline *PTPN11* mutations, leading to the concept that only milder SHP-2 activation may be tolerated during embryonic development [59–61]. Interestingly, in addition to JMML, gain-of-function mutations in *PTPN11* have been rarely associated with other hematologic malignancies in children or adults [62].

PTPase SHP2 plays a crucial role in physiologic hematopoiesis and hematopoietic stem-cell function; endogenous expression of gain-of-function mutants in mice reduces hematopoietic stem-cell repopulating activity and promotes mobilization of stem cells from the bone marrow to the spleen [62]. Whereas the endogenous expression of gain-of-function Shp2D61Y induces myeloproliferation, but not acute leukemia [63], the gain-of-function Shp2E76K mutation results in a myeloproliferative disease that progresses to acute leukemia of multiple lineages [64].

Germline *CBL* mutations and loss of heterozygosity

CBL was originally discovered as the cellular homolog of the *V-Cbl* oncogene, the transforming gene of the Cas NS-1 murine retrovirus that causes myeloid leukemia in mice. It encodes a member of a family of RING finger proteins, which functions as an E3 ubiquitin ligase. CBL negatively regulates signaling by tyrosine kinases and functions as an adapter protein to regulate signaling positively [65]. Using single nucleotide polymorphism arrays, copy-neutral loss of heterozygosity based on UPD at chromosome 11q identified *CBL* mutations in myeloid neoplasm and JMML [66]. In JMML, the *CBL* mutations were found to target preferentially amino acid Y371 in the linker region, whereas mutations affecting this amino acid are rare in other myeloid neoplasms [67]. The exclusivity of *CBL* mutations with respect to other RAS pathway-associated mutations indicated that *CBL* plays a role in deregulating the RAS pathway in JMML [66,68,69].

Subsequently, it was shown that children with JMML and *CBL* mutations have germline missense *CBL* mutations and display several congenital anomalies that overlap with NF1, NS, and Legius syndrome [16]. Individuals with germline *CBL* mutations are at increased risk of developing loss of heterozygosity for the *CBL* locus in hematopoietic stem or progenitor cells. The resulting myeloproliferative disorder either may be self-resolving or follow an aggressive clinical course [16,66,70,71].

Secondary mutations

While mutually largely exclusive mutations in *NF1*, *PTPN11*, *KRAS*, *NRAS*, and *CBL* are noted in 90% of CMML patients, alterations seen in other myeloproliferative disorders such as JAK-2 [72–74], TET-2 [75,76], ASXL2 [76,77], SETBP1 [78], and JAK-3 [78] are rare, as are *FLT3* mutations [79,80].

Natural course and prognostic factors

JMML is a rapidly fatal disorder for most children if left untreated. Low platelet count, age above 2 years at diagnosis, and high HbF at diagnosis are the main predictors of short survival (Figure 49.3) [3,6,8]. In a retrospective series of 110 cases, all children presenting with a platelet count of 33×10^9/L or less had died within 1 year from diagnosis, whereas those with higher counts and age less than 2 years at diagnosis had a median survival of 3 years [8]. British investigators devised a scoring system, where HbF of 10% or higher and a platelet count of 33×10^9/L or less negatively affect prognosis [6]. Blastic transformation is infrequent in JMML, and most untreated patients succumb to respiratory failure due to pulmonary infiltration of mature leukemic cells.

As outlined above, there are rare patients with somatic mutations in *NRAS* [52] and possibly *KRAS* [46,47] who experience spontaneous resolution of their JMML despite persistence of the mutated clone. Low HbF and high platelet counts will be helpful in distinguishing these few cases from the generally fatal courses of JMML.

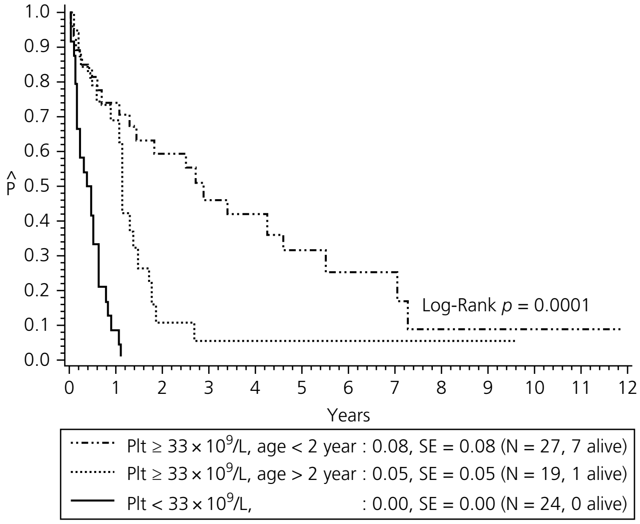

Figure 49.3 Survival of patients without bone marrow transplantation according to platelet count and age at diagnosis [8].

In addition, children with germline *PTPN11*, *NRAS* and *KRAS* mutations and myeloproliferation generally show amelioration with time and do not require HSCT [28]. The same applies to most children with germline *CBL* alterations.

On a molecular level, gene expression studies found that patients with JMML could be separated into two prognostic groups. Interestingly, the profile of JMML cells in cases with poor prognosis was reminiscent of that of acute myeloid leukemia (AML) cells. The 10-year event-free survival (EFS) after HCT was 6% for AML-like and 63% for non-AML-like patients [81]. Furthermore, epigenetic alterations were shown to be associated with outcome [82]. Using MassARRAY, JMML cells were analyzed for aberrant DNA methylation at four gene loci. Hypermethylation was noted in 13–54% of JMML cases and, in multivariate analysis, this epigenetic characteristic retained prognostic value for survival and relapse post-HCT independently of other clinical risk factors [82].

Non-transplant approaches

To ameliorate disease activity prior to HCT, a great variety of antineoplastic drugs and combination-type therapies have been applied in JMML in the past [31]. Clinical and hematologic responses in JMML have most consistently been obtained with mercaptopurine, administered either as a single agent or in combination with low-dose cytarabine or etoposide. There are, however, no data indicating that therapy with mercaptopurine influences the duration of survival.

Clinical remissions and long-term survival after AML-type combination therapy have been reported in small series [31]. Study CCG 2891 of the Children's Cancer Study Group for treatment of childhood AML, MDS, and JMML included 13 children with JMML [83]. Seven of the 12 JMML patients receiving intensive induction chemotherapy achieved hematologic remission. Other investigators have pointed out that intensive chemotherapy is notably unsuccessful in patients with aggressive disease, and durable remissions may not be achievable [31]. A recent phase II trial sponsored by the Children's Oncology Group (COG) utilized cytoreductive therapy consisting of fludarabine and high-dose cytarabine concomitantly [40].

Data from culture studies showing inhibition of JMML colony formation prompted the clinical utilization of interferon-α and 13-*cis*-retinoic acid [84,85]. While a prospective study with interferon-α sponsored by the Pediatric Oncology Group was stopped owing to excessive toxicity [86], preliminary results on 10 children with JMML treated with isoretinoin 100 mg/m^2 daily were promising [87]. However, a large proportion of these children were below the age of 2 years, a factor known to characterize patients with a less aggressive course. In a subsequent phase II window trial of the COG, 22 evaluable patients were accrued: five complete and four partial responses were noted [88]. Other investigators did not observe significant clinical responses with retinoic acid [89], and its value in JMML remains questionable.

Because aberrant DNA methylation is a strong predictor of poor outcome in JMML [82], epigenetic therapeutic approaches may be promising. One of the agents, azacitidine, is believed to exert its antineoplastic effects by multiple mechanisms including cytotoxicity on abnormal hematopoietic cells in the BM and hypomethylation of DNA. The cytotoxic effects of azacitidine may result from multiple mechanisms, including inhibition of DNA, RNA, and protein synthesis, incorporation into RNA and DNA, and activation of DNA damage pathways. Incorporation of azacitidine into DNA results in the inactivation of DNA methyltransferases, leading to hypomethylation of DNA. DNA hypomethylation of aberrantly methylated genes involved in normal cell cycle regulation, differentiation, and death pathways may result in gene re-expression and restoration of cancer-suppressing functions to cancer cells. Following an intriguing case of JMML and clonal monosomy 7 with complete hematologic and molecular response to azacytidine [90], a phase I/II study with azacitidine was initiated by the European Working Group of Myelodysplastic Syndromes in Childhood (EWOG-MDS) and the Consortium for Innovative Therapies for Children with Cancer (ITCC) (NTR2578). Azacytidine may be a viable option for JMML patients, either as a pre-transplant window or in the absence of a suitable HCT donor.

In summary, most investigators prescribe 6-mercaptopurine for pre-transplant therapy in children with JMML. Single doses of low-dose cytarabine are added if more cytoreduction is needed. In critically ill children, the combination of fludarabine and high-dose cytarabine can be lifesaving, although rapid leukemic regrowth is common. The response to demethylating agents is promising and will need confirmation in clinical studies.

Therapy targeting Ras-dependent pathways

The understanding of the important role of GM-CSF and the downstream RAS signaling transduction pathway has led to the design of therapeutic strategies targeting individual components of the pathway. The GM-CSF receptor has been targeted by the GM-CSF analog E21R. In a child with JMML relapsing after HCT, the administration of two cycles of E21R resulted in a transient clinical and hematologic response lasting for about 60 days [91]. RAS proteins are synthesized as precursor molecules in the cytoplasm, becoming activated in part by the addition of farnesyl moiety catalyzed by the enzyme farnesyl-protein transferase. Farnesyltransferase inhibitors (FTIs) can reduce JMML colony formation in vitro but did not inhibit leukemic infiltration in *Nf1*$^{-/-}$ mice [92]. In an up-front phase II window the Children's Cancer Group (CCG) studied the effects of the FTI tipifarnib (FTI R115777) in newly diagnosed patients with JMML [93]. The overall response rate was based on changes in WBC count and organomegaly. Among the 38 patients receiving more than two courses, 22 had a complete or partial response. There was no relationship between farnesyl-protein transferase inhibition or response and the presence of *RAS/PTPN11* mutation or inhibition of prenylation in vitro [93]. Furthermore, there was no impact on survival [40].

The two effector pathways of RAS signaling, the Raf/MEK/ERK cascade and the P*i*3K/Akt/mTOR pathway, are logical potential therapeutic targets in JMML. Agents specifically designed to target components of these cascades are still to be studied in the future. Although these strategies may not be sufficient to abolish the malignant clone by themselves, they could have an important role in future regimens of multimodality therapy. In this respect, rapamycin, an mTOR inhibitor, is integrated as immunosuppressive therapy and minimal residual agents post-HCT in the current COG trial ASCT1221 [40].

Hematopoietic cell transplantation

Early experiences

The first HCT in JMML was reported by the group in Seattle in 1979 [94]. Subsequently, in 1988, the same investigators published data on a series of 14 children including the first case. These early experiences indicated that HCT was capable of curing approximately one-third of the children with JMML. Relapse was the major cause of treatment failure and occurred early in the post-transplant course. In contrast, non-relapse mortality (NRM) in this young patient population was low. Partially matched family member donors and unrelated donors (URDs) were introduced in JMML transplantation in the early 1980s. In a retrospective multicenter review of 43 children treated with HCT between 1987 and 1995, and registered to the EWOG-MDS database, the probability of EFS for 18 patients transplanted from a matched URD or a two- to three-antigen-disparate relative was 22% at 5 years, compared with 38% for 25 patients transplanted from an HLA-identical sibling donor ($p < 0.5$) [95]. With the exclusive application of molecular typing the outcome of HCT with URD has improved considerably.

Preparative regimen

During the early experiences, most children with JMML undergoing HCT received total body irradiation (TBI) as part of their preparative regimen. There have been a number of reports indicating more deleterious long-term morbidity in young children after TBI compared with busulfan (BU)-based regimens [96]. Since there are no reports indicating that TBI offers an advantage over a BU-containing preparative regimen, to avoid severe radiation-induced growth retardation, endocrine and neuropsychologic sequelae, and second malignancies, several groups introduced non-TBI preparative regimens for HCT in JMML [97–100]. Most investigators chose BU and cyclophosphamide (CY) combined with etoposide (VP16) [100] or melphalan [95,97,101], whereas others employed BU, cytarabine (Ara-C), and melphalan [102].

In a retrospective study on 27 children with JMML transplanted between 1990 and 1997 in Japan, the probability of EFS at 4 years was 54%, with no difference in outcome between TBI and non-TBI regimens. In contrast, the retrospective EWOG-MDS study demonstrated for the group of children given HCT from an HLA-identical sibling or a one-antigen-disparate relative that the use of BU was associated with a lower probability of relapse (38% versus 78%, respectively), which resulted in a significantly better EFS in comparison with the use of TBI (62% versus 11%, respectively, $p < 0.01$) [95]. A significantly higher relapse rate in patients prepared with TBI was also demonstrated in a literature review on 65 children with JMML transplanted prior to 2000 [103].

The EWOG-MDS chose a preparative regimen consisting of the three alkylating agents BU, CY, and melphalan [97]. Melphalan had been shown to increase the antileukemic efficacy of a BU–CY regimen in children given an unpurged autologous HCT [104]. In addition, a preparative regimen consisting of three alkylating drugs that have non-cell-cycle-specific action appears potentially capable of eradicating stem-cell disorders, such as JMML, in which at least a portion of clonogenic cells are dormant out of cell cycle. In the currently largest prospective study, 100 consecutive JMML patients registered at EWOG-MDS were given unmanipulated grafts after a preparative regimen with BU 16 mg/kg, CY 120 mg/kg, and melphalan 140 mg/m^2. All but three children experienced prompt engraftment. The 5-year probability of EFS for 48 patients given a graft from an HLA-identical sibling and for 52 children transplanted from an HLA-matched or one antigen/allele-disparate URD was 55% [95% confidence interval (CI) 41–70%] and 49% (95% CI 5–63%), respectively (p = NS) [101]. With a cumulative incidence of NRM of 13%, and no significant difference between sibling and URD transplants, this result indicates that the preparative regimen was safe. In addition, it confirmed that, in the last 15 years, the use of URDs has offered minimal or possibly no significant disadvantage compared with employing an HLA-identical sibling [99]. Figure 49.4 gives an update for EFS, NRM, and relapse incidence for the EWOG-MDS study [101] after a median observation time of patients alive of 5.8 years (range 2.3–12 years). Based on the results of EWOG-MDS, the North American Children's Oncology Group (COG) is currently studying whether a conditioning regimen with BU and fludarabine will have less NRM and comparable EFS compared with the BU–CY–melphalan preparative regimen.

Non-relapse mortality

With current supportive care, recent multicenter trials indicated that the probability of NRM in patients transplanted for JMML is not influenced by the use of either an HLA-identical sibling donor

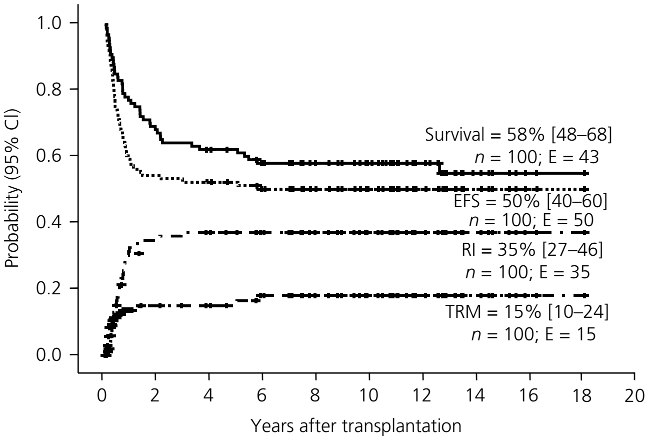

Figure 49.4 Five-year overall survival, event-free survival (EFS), relapse incidence (RI), and transplant-related mortality (NRM) of 100 children with JMML transplanted after a conditioning regimen including busulfan, cyclophosphamide, and melphalan from a matched related ($n = 48$) or a matched unrelated ($n = 52$) donor. Update with a median observation time of patients alive of 11.1 years (range 3.9–18.5 years) of data published by Locatelli et al. [101].

or a URD, with results of 11% [99], 13% [101], and 18% [105]. A similar NRM of 16% has been reported from the large retrospective analysis of umbilical cord (UCB) transplantation for children transplanted after 2003 [106]. This surprisingly low mortality in a generally much compromised patient population transplanted with an intensive preparative regimen might be explained by the young patient age and the experience of centers dedicated to HCT in infants.

Relapse

Relapse is the major cause of treatment failure in patients with JMML undergoing HCT [95,99,101,105]. It generally occurs within the first year after transplantation, the peak being observed after a median time of 2–6 months [101,105,106]. Older age [95,99,101], increased percentage of HbF [101,105], abnormal karyotype [99,106], and blast percentage above 20% [101] have been identified as patient-specific risk factors for disease recurrence. Age above 2 years at diagnosis and a high HbF have been found to predict short survival also in studies analyzing the natural history of JMML in patients not treated with HCT [3,6,8].

In the multivariate analysis of the prospective EWOG-MDS study, age remained the major significant factor for prediction of disease recurrence. The cumulative incidence of relapse for children less than 2 years of age at diagnosis, 2–4 years, and older than 4 years was 18% (95% CI 10–32%), 46% (95% CI 30–70%), and 73% (95% CI 53–98%), respectively, resulting in a probability of EFS of 64% (95% CI 51–76%), 50% (95% CI 31–70%), and 16% (95% CI 0–34%), respectively [101]. An update on these data with a median observation time of patients alive of 5.8 years (range 2.3–12 years) is shown in Figure 49.5. The poor outcome for older children with JMML demands new strategies such as a better preservation of a graft-versus leukemia (GVL) effect. It also points to the fact that HCT shortly after diagnosis is indicated even in patients less than 1 year of age.

As mentioned above, an AML-like gene expression profile and an aberrant hypermethylation of certain genes predict an increased risk of disease recurrence [87,88].

Graft-versus-host-disease and graft-versus-leukemia-effect

The most frequently used regimens for graft-versus-host disease (GVHD) prophylaxis consist of cyclosporine (CSP) for patients transplanted from an HLA-identical sibling donor, and of CSP with methotrexate and antithymocyte globulin for URD transplantation [101,106]. The prospective EWOG-MDS study reported a cumulative incidence at day 100 of grade II–IV GVHD of 40% (range 31–51%), whereas that of grade III–IV acute GVHD was 17% (range 11–26%) [101]. There was no difference in the incidence of grade II-IV GVHD between matched sibling donor (46%) and URD donor (35%) transplant recipients (p = NS). No patient- or transplantation-related variable was significantly associated with the development of acute GVHD in multivariate analysis [101]. Acute GVHD grade III–IV has been associated with poor overall survival in JMML patients [99,105].

Owing to the young age of JMML patients, incidence rates for acute and chronic GVHD tend to be lower than in other leukemic diseases. Chronic GVHD in children transplanted for JMML has been reported in 17% of children at risk in the prospective EWOG-MDS study [101], in 25% of patients in the NMDP cohort [105], and in 10 of 24 cases in the Japanese review [99]. Interestingly, in contrast to EWOG-MDS reporting the lowest cumulative incidence of chronic GVHD, investigators from the United States and Japan noted a better overall survival for children suffering from chronic GVHD compared with those without [99,105]. These data suggest a possible GVL effect directed against JMML cells. A number of reports have described the efficacy of withdrawal of immunosuppressive therapy in patients with incipient relapse of JMML [103]. In addition, less intensive GVHD prophylaxis is generally employed during second HCT, a procedure resulting in long-term survival similar to that of first HCT despite the use of the same donor [107]. Taken together, there is sufficient evidence that GVL plays a major part in eradicating JMML cells following allogeneic transplantation. Not surprisingly, HCT after in vitro depletion of donor T-lymphocytes is hampered by a high relapse rate (EWOG-MDS Registry, unpublished observation).

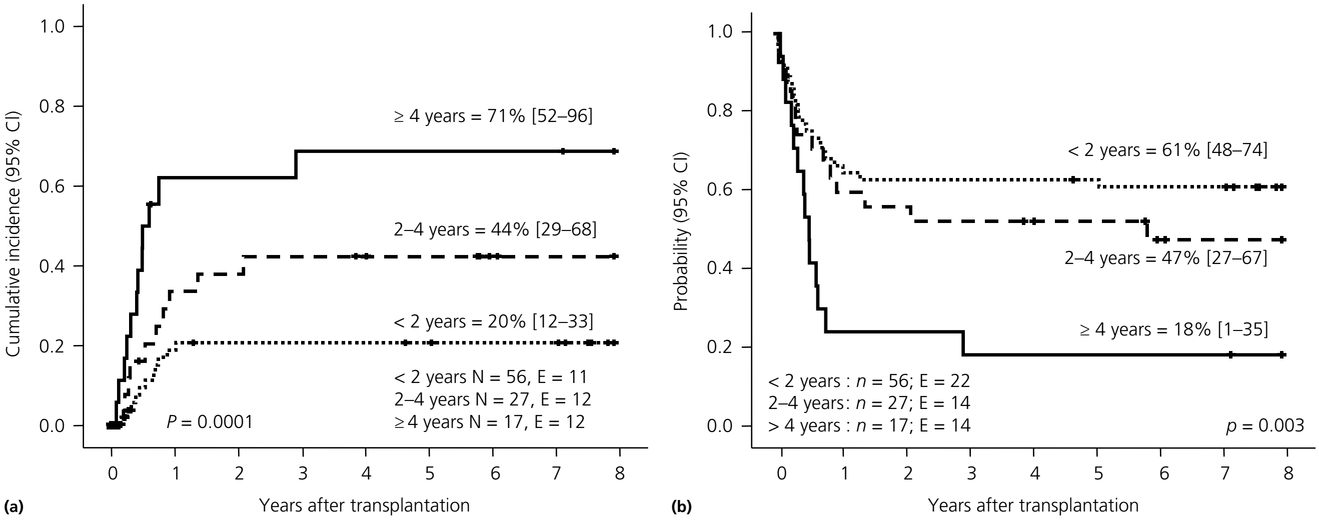

Figure 49.5 Relapse incidence (a) and event-free survival (b) by age at diagnosis of 100 children with JMML transplanted after a conditioning regimen including busulfan, cyclophosphamide, and melphalan from a matched related ($n = 48$) or a matched unrelated ($n = 52$) donor. Update with a median observation time of patients alive of 11.1 years (range 3.9–18.5 years) of data published by Locatelli et al. [101].

Stem-cell source and umbilical cord blood transplantation

Most HCT in JMML has been performed with unmanipulated BM cells. HCT with peripheral blood hematopoietic cells does not result in a better overall survival or lower relapse rate [101]. In the last two decades, UCB from a URD has been increasingly used as an alternative source of hematopoietic stem cells. Major advantages of UCB compared with BM in this young patient population generally in urgent need for HCT are rapid availability of stem cells and the possibility of using donors with HLA disparity with respect to the recipient. Although UCB transplantation in JMML had been successfully performed [101,108,109], there was concern that it may have an insufficient GVL effect for this aggressive form of leukemia. A recent retrospective analysis on behalf of Eurocord, the European Group for Blood and Marrow Transplantation, EWOG-MDS, and the Center for International Blood and Marrow Transplant Research on 110 children with JMML given a single-unit unrelated donor UCB demonstrated outcomes similar to what has been reported with different sources of donors of hematopoietic stem cells [106]. With a median follow-up of 64 months, the 5-year probability of overall survival was 52% (95% CI 47–59%). Better outcome was associated with age at diagnosis younger than the median age of 1.4 years, use of donor with either 0 or 1 HLA disparity with the recipient, and a karyotype other than monosomy 7 [106]. Despite a greater HLA disparity, the probabilities of grade II–IV acute GVHD (41%, 95% CI 37–45%) and chronic GVHD (15%, 95% CI 11–19%) were similar to those reported in studies employing HLA-matched BM or peripheral blood cells. There was a trend for an increased risk for NRM of patients given UCB transplantation before 2003, the 95% CI of NRM being 11–21% for children receiving grafts after 2003 and 23–35% for those given UCB transplantation before 2003 [106]. Thirty-seven patients relapsed at a median of 2.6 months; the 5-year cumulative incidence of relapse was 33% (95% CI 28–38%) [106], a value similar to what has been reported in studies using BM grafts. Because there is experimental evidence that the presence of two competing UCB grafts elicits powerful cytotoxic reactions during early post-HCT phase, double cord transplantation had been advocated in cases of disease occurrence following a first allograft [110]. Overall, the available evidence indicates that UCBT is a suitable option for a large proportion of children with JMML lacking an HLA-identical sibling donor. A search for a suitable unrelated cord blood unit should be initiated simultaneously with that for locating an HLA-matched unrelated BM donor.

Chimerism studies and MRD

As in other hematologic malignancies, serial quantitative chimerism studies using a small number of tandem repeat markers have been shown to identify patients with increasing mixed chimerism who are at high risk for relapse following transplantation for JMML [111]. Because it could be demonstrated that rapidly increasing mixed chimerism is invariably followed by relapse of JMML [111], immediate withdrawal of immunosuppressive therapy is indicated after the first detection of mixed chimerism. This maneuver appears safe and effective, although a number of cases of successfully sustained remission have been reported to be associated with chronic GVHD [112]. In some patients, rapid progression of disease occurs in the absence of a previously documented mixed chimerism status. More sensitive methods, such as the application of disease-specific markers, may increase sensitivity, thus allowing the detection of a smaller percentage of residual leukemic cells. For this purpose, a fluorescently based, allele-specific polymerase chain reaction assay to detect the most common *RAS* or *PTPN11* mutations was developed [113]. Prospective studies will be required to demonstrate whether this method will allow modification of post-transplant immunosuppression early enough to prevent hematologic relapse.

Donor lymphocyte infusion

Treatment options for JMML patients relapsing after HCT are limited. Withdrawal of immunosuppressive drugs is usually the first measure, which by itself can control leukemia in a limited number of patients [103,112,114], suggesting a GVL effect in JMML. In case of non-response and for patients suffering disease recurrence after discontinuation of immunosuppressive agents, donor lymphocyte infusion (DLI) or second HCT may be considered. There are several reports on successful therapy with DLI of relapsed JMML [112,115–117]. Two of three patients with chromosomal studies reported had a normal karyotype, one monosomy 7. Following chemotherapy ($n=2$) or splenectomy ($n=1$), DLI from the matched ($n=2$) or one HLA locus-mismatched ($n=1$) URD had been administered. GVHD was observed in two patients and BM failure in one, and all patients were alive at the time of reporting. These case reports suggest that at least some relapsed JMML patients can benefit from DLI. However, reporting bias is likely to exaggerate the benefit of this form of therapy in single successful cases. In this respect, in a retrospective study from EWOG-MDS, the efficacy of DLI was studied in 21 JMML patients receiving DLI for mixed chimerism ($n=7$) or relapse ($n=14$) [114]. Response rates were significantly higher in patients receiving a higher total T-cell dose ($\geq 1 \times 10^7$/kg) and in patients with an abnormal karyotype. None of the six patients receiving DLI from an HLA-identical sibling donor responded. In total, six of the 21 patients responded to DLI, but only one of the responders remained alive in remission, two relapsed, and three died of complications. Although JMML can be sensitive to DLI, the overall outcome of patients responding to DLI is poor due to complications and relapse.

Second transplantation

Several large reports on the results of second HCT for relapse after first HCT in patients with various types of leukemia have been published. These analyses generally show a poor outcome with a high rate of relapse and NRM. Because relapse remains the major cause of transplant failure in children with JMML, second HCT had been attempted in a number of patients. Chang et al. reviewed the reports on 13 patients undergoing second transplantation, seven of whom were alive and disease free with a median follow-up of 53 months [118]. A retrospective review of EWOG-MDS confirmed that second HCT can be an effective salvage therapy for children with JMML relapsing after a first grafting procedure [107]. Twenty-four patients were given a second allograft for relapse diagnosed at a median of 160 days after first HCT. The median time between first and second HCT was 260 days. The same donor was employed for both first and second HCT in 19 of the 24 patients. Ten patients (43%) were alive in remission after a median observation time of 3.3 years. The probability for leukemia-free survival at 3 and 5 years was 50% (95% CI 30–70%) and 32% (95% CI 8–56%), respectively. Although none of the six patients who developed chronic GVHD after the second HCT experienced leukemia recurrence, eight of 14 patients without chronic GVHD relapsed after the second HCT ($p=0.04$). It is reasonable to speculate that reduced immunosuppressive therapy employed during the second grafting procedure resulted in a stronger GVL effect and favorable outcome. Eighteen of the 24 patients had received a BU-containing regimen for first

HCT and a TBI-based regimen for second HCT, and nine of 18 were alive in remission. A report on HCT in JMML from the Seattle group included six patients who underwent a second allograft, using TBI–CY ± BU and BU–CY regimens for the first and second HCT, respectively [119]. Only one of the six patients was alive in remission after the second HCT. Promising, although still preliminary, results have been obtained using treosulfan-based regimens (EWOG-MDS Registry, unpublished results). In conclusion, current results on second HCT in JMML are superior to those obtained with DLI and, surprisingly, similar to those reported for first HCT.

Splenectomy and other treatment prior to transplantation

Although some investigators have suggested that aggressive chemotherapy can ameliorate the disease in some children with JMML [83], there is no evidence that it reduces relapse incidence or improves survival following transplantation [101]. Therefore, intensive chemotherapy prior to HCT for JMML is not recommended by most investigators. Likewise, none of the other therapy approaches has been shown to have an impact on post-transplant survival. Whether epigenetic drugs, such as 5-azacytidine, or agents targeting the RAS pathway prior to HCT may be beneficial is currently unknown. Splenectomy remains a controversial intervention for children with JMML. In Philadelphia chromosome-positive CML, it has not been shown to improve survival after allogeneic HCT. However, gross enlargement of the spleen may give rise to abdominal discomfort and excessive transfusion requirements. Therefore, early splenectomy has been recommended for amelioration of the disease, and in the last study of the COG, all clinically stable patients were scheduled for splenectomy. In a retrospective study of 72 children with JMML who received HCT, splenectomy prolonged survival independently of other risk factors (authors' own unpublished observations). Although it has been common practice to remove large spleens prior to HCT [95], the benefit of splenectomy for prevention of post-transplant relapse is unknown [98]. In the prospective EWOG-MDS study, splenectomy before HCT, and also spleen size at time of the allograft, did not have an impact on post-transplantation survival, relapse rate, or time to engraftment [101]. Similarly, splenectomy did not influence survival in the large retrospective analyses on UCB transplantation in JMML [106]. Results of these large cohorts are not in favor of the indiscriminate use of splenectomy before transplantation. Splenectomy at a young age is associated with an increased risk of life-threatening infections. The indication of performing splenectomy has to be carefully evaluated for each individual child. The presence of massive splenomegaly with evidence of hypersplenism and/or refractoriness to platelet transfusion can be an argument for considering this procedure in order to promote engraftment, to hasten hematologic recovery, and to lower the risk of hemorrhagic complications.

Outlook

Currently, about 60% of children with JMML can be cured following first or second HCT. Reduction of relapse incidence for older children continues be one of the major challenges for future clinical trials. Less immune-suppressive therapy for GVHD prophylaxis and careful monitoring of MRD following transplantation could be instrumental in reducing the relapse risk. Preparative regimens with better antileukemic efficacy can be designed, but major advances in transplant biology in children with JMML may depend on new insights into the etiology and molecular genesis of the disease.

CHAPTER 50

Hematopoietic Cell Transplantation for Adult Acute Myeloid Leukemia

Frederick R. Appelbaum
Fred Hutchinson Cancer Research Center and University of Washington School of Medicine, Seattle, WA, USA

Introduction

Acute myeloid leukemia (AML) defines a spectrum of myeloid malignancies with many common features but also considerable variability in underlying biology and clinical outcomes. Because the majority of patients will not be cured with conventional chemotherapy, hematopoietic cell transplantation (HCT) plays an important role in the management of this disease. However, given the multiple forms of transplantation available (allogeneic related, allogeneic unrelated, autologous, reduced intensity, etc.), together with the variability in AML, careful evaluation and planning are required to integrate HCT optimally into the care of each patient.

Epidemiology and etiology

In 2015, approximately 20,830 Americans will develop AML. The incidence of AML is roughly constant over the first three decades of life and then increases almost exponentially [1]. In most cases, no clear etiology can be found. A genetic predisposition exists in some individuals. The concordance rate between identical twins approaches 100% if AML develops within the first year of life, but subsequently declines with age. “Pure familial leukemias” are rare syndromes without other manifestations caused by single mutations in several genes, including *RUNX1*, *CEBPA*, and *GATA2*. An increased incidence of AML is seen in the RNA-ribosomal bone marrow failure syndromes, Diamond–Blackfan, Shwachman–Diamond, and dyskeratosis congenita, and also in syndromes associated with defective DNA repair, including Fanconi anemia and Bloom syndrome. AML is also increased in Li–Fraumeni syndrome and in syndromes associated with abnormal chromosome numbers, including 21+ and XXY.

Environmental exposure to benzene or benzene-containing solvents has been associated with an increased incidence of myelodysplasia and AML. The incidence of AML is doubled in cigarette smokers. With increasing use of radiation and chemotherapy to treat malignancy, treatment-related AML has become more frequent and now accounts for 6–8% of AML cases [2]. AML following alkylating agent exposure typically has a latency period of 5–7 years and first appears as a myelodysplastic syndrome (MDS) with abnormalities of chromosomes 5 and 7. AML following topoisomerase II exposure has a shorter latency without an MDS prodrome and often has chromosomal abnormalities involving 11q23. However, following combination chemotherapy, many cases of treatment related AML fail to fall into a discrete category. In general, patients with treatment-related AML respond less well to therapy than patients with de novo AML, even after adjusting for other known risk factors.

Other myeloid malignancies eventually evolve into AML. This commonly occurs in the MDSs, occasionally happens with polycythemia vera and idiopathic myelofibrosis, and rarely is seen in essential thrombocythemia. AML arising from an antecedent hematologic malignancy usually has trilineage dysplasia and frequently has unfavorable cytogenetic changes. Approximately 3% of AMLs in patients under age 60 years and as many as 15% of cases over age 60 years arise from a prior myeloid malignancy.

Molecular and cellular biology

Cell of origin

AML is a clonal disorder, with all leukemia cells in an individual patient descending from a common precursor. The initial proof of clonality in AML came from studies of the disease in females who were heterozygotic for the X-linked glucose-6-phosphate dehydrogenase isoenzyme. Whereas normal hematopoietic cells in such individuals would be a 50:50 mix of the two isoenzymes, leukemia cells are all of one isoenzyme or the other, indicating their clonal origin. Recent genome-wide analyses of AML have demonstrated considerable complexity with a number of recurrent potential “driver” mutations in each individual case. Further studies of individual cells within single cases of AML have found considerable mutational variability from cell to cell, suggesting that the development of AML is not a simple progressive accumulation of mutations in a liner direction, but rather a dynamic process with multiple cycles of mutation acquisition and clonal selection [3].

Within the clonal population of AML, there must be a subpopulation of cells capable of both self-renewal and proliferation. Efforts to identify the nature of such “AML stem cells” have been based on the ability of a cell to establish leukemia when transferred to an immunodeficient mouse. Such studies indicate that leukemia stem cells make up a relatively rare subpopulation of the leukemia, accounting for only 0.2–100/10^6 leukemic cells, and have a primitive CD34^{++}CD38^{-} phenotype, no matter what the degree of differentiation of the rest of the leukemia cells is [4]. However, defining a leukemic stem cell by its ability to engraft in an immunodeficient mouse is admittedly arbitrary and may not identify a true AML stem cell.

Pathology

Although the leukemia stem cell may have a primitive phenotype, the bulk of leukemia cells in any individual will exhibit morphologic evidence of some differentiation. For more than three decades, the French–American–British (FAB) system was used to classify AML, dividing cases among eight categories (M0 to M7) according to the degree of differentiation and lineage [5]. The prior FAB system has since been incorporated as part of the newer World Health Organization (WHO) Classification of AML (see Table 50.1). AML morphology is of little significance once the underlying molecular abnormality is taken into consideration.

Immunophenotype

AML blasts can be defined according to the combination of myeloid-associated antigens expressed on the cell surface. The most immature cases express CD34, CD117, and HLA-DR. CD13 and CD33 are pan-myeloid markers and are present on the surface of most cases of AML. CD14, CD15, and CD11b are associated with monocytic differentiation. CD36 and CD71 are associated with erythroid leukemia whereas CD41a and CD61 are associated with megakaryocytic leukemia. In 10–20% of cases, AML blasts express a single B- or T-cell-associated antigen (CD19 or CD2), but this is of no apparent clinical significance. However, in rare cases, AML blasts express multiple lymphoid markers. Such cases of mixed-phenotype acute leukemia have a poor prognosis. Immunophenotyping of AML has several uses. It can confirm the distinction between AML and acute lymphocytic leukemia, and it has some weak prognostic power. Most commonly, however, since AML cells virtually always have an immunophenotype distinct from that of normal cells, immunophenotyping in the context of multidimensional flow cytometry (MFC) is used as a method of detecting minimal residual disease (MRD).

Table 50.1 World Health Organization classification of acute leukemia with corresponding FAB classification subtypes (2008)

- AML with recurrent genetic abnormalities
  - AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
  - AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
  - APL with t(15;17)(q22;q12); *PML-RARA*
  - AML with t(9;11)(p22;q23); *MLLT3-MLL*
  - AML with t(6;9)(p23;q34); *DEK-NUP214*
  - AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
  - AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*
  - *Provisional entity: AML with mutated NPM1*
  - *Provisional entity: AML with mutated CEBPA*
- AML with myelodysplasia-related changes
- Therapy-related myeloid neoplasms
- Acute myeloid leukemia, not otherwise specified
  - AML with minimal differentiation
  - AML without maturation
  - AML with maturation
  - Acute myelomonocytic leukemia
  - Acute monoblastic/monocytic leukemia
  - Acute erythroid leukemia
    - Pure erythroid leukemia
    - Erythroleukemia, erythroid/myeloid

- Myeloid proliferations related to Down syndrome
  - Transient abnormal myelopoiesis
  - Myeloid leukemia associated with Down syndrome
- Blastic plasmacytoid dendritic cell neoplasm

Molecular pathology and cytogenetics

Animal models of AML suggest that most cases require multiple mutations for full expression of the disease, including mutations that block differentiation and others that result in inappropriate proliferation. These mutations can be divided into those that are recognizable by particular chromosomal abnormalities and those that require other molecular studies for their recognition.

Recurrent cytogenetic abnormalities

Core binding factor (CBF) translocations

CBFα (also known as RUNX-1) and CBFβ normally combine to form a heterodimeric transcription factor required for hematopoietic differentiation. The t(8;21) abnormality seen in 8% of adult AML cases results in fusion of the gene encoding CBFα on chromosome 8 (*RUNX*-1) with a gene (*MTG8*) on chromosome 21. Inv(16) seen in approximately 7% of AMLs, results in the fusion of the gene encoding CBFβ to the smooth muscle myosin heavy-chain gene. In both cases, the resulting abnormal fusion protein acts as a dominant negative regulator of transcription. As will be discussed in more detail, CBF AMLs tend to occur in younger individuals and have a relatively favorable prognosis [6].

Retinoic acid receptor α translocations

Acute promyelocytic leukemia (APL) represents about 8% of adult AML cases and is essentially always associated with t(15;17), a translocation which fuses the promyelocytic leukemia gene (*PML*) on chromosome 15 with the retinoic acid receptor alpha gene (*RARα*) on chromosome 17. The resultant PML/RARα fusion protein acts as a dominant negative, in part by recruiting nuclear corepressor and the molecules sin3 and histone deacetylase [7]. All-*trans*-retinoic acid (ATRA) appears to have unique activity in this disease by virtue of its ability to bind to the fusion protein, resulting in a change in its configuration and release of the attached nuclear corepressors. Other rare translocations involving *RARα*, including t(11;17) and t(5;17), give rise to leukemia that clinically resembles APL but is much less responsive to ATRA.

Mixed-lineage leukemia mutations

Translocations involving 11q23 are seen in approximately 7% of adult AML cases. Although t(9;11) is the most common, t(6;11), t(10;11), t(11;17), and t(11;19) are also seen. Murine studies suggest that the *MLL* gene product positively regulates homeodomain (*HOX*) genes, which are required for normal development. Thus, a current hypothesis is that MLL fusion proteins result in increased expression of *HOX* genes resulting in increased self-renewal [8].

Chromosomal abnormalities involving 5q, 7q, and 20q

Abnormalities in 5q, 7q, or 20q are particularly frequent in AML in the elderly, AML secondary to prior exposure to alkylating agents, and AML following MDS [9]. These leukemias have a relatively poor prognosis. Although it has been hypothesized that the recurrent appearance of these abnormalities might be explained by the existence of classic tumor suppressor genes at these locations, no such genes have been identified.

Mutations not detectable on routine cytogenetics

Tyrosine kinase receptor mutations

Receptor tyrosine kinases are a family of proteins with extracellular, transmembrane, and intracellular domains with tyrosine kinase activity. Ligand binding of these proteins leads to receptor dimerization and subsequent phosphorylation of adaptive proteins, which in turn activate RAS and other downstream proteins. Activating mutations in *FLT3*, a prototypic receptor tyrosine kinase, are found in 30–35% of AML patients. The majority of mutations are internal tandem duplications (ITDs), and approximately 25% of mutations are point mutations. The incidence of *FLT3* mutations is higher in older individuals and those with higher white blood cell (WBC) counts at diagnosis. The presence of *FLT3* mutation implies a poorer outcome with conventional chemotherapy, and this trend is increased with increasing size of the ITD and with higher allelic ratios of mutated to wild-type genes in marrow specimens. Mutations in other receptor tyrosine kinases are sometimes seen in AML, including mutations in *FMS* and *KIT* [10].

RAS mutations

RAS is a guanosine diphosphate-binding protein activated by various tyrosine kinases. Activation of RAS has multiple effects depending on the cell and its particular state, but can result in cellular proliferation and transformation. Mutations in RAS are found in 15–20% of AML cases. Such mutations prevent hydrolysis of RAS-GTP, thereby keeping RAS in the "on" position. For normal function, RAS must have a farnesyl or geranylgeranyl lipid attached, so compounds that inhibit farnesylation have been studied as possible therapies in AML.

NPM1 mutations

NPM1 encodes a nucleolar phosphoprotein with multiple hypothesized functions. *NPM1* is mutated in 30% of AML cases and is associated with monocytic differentiation, normal cytogenetics, and an improved overall prognosis.

C/EBP alpha mutations

C/EBP alpha stands for CCAAT/enhancer binding protein alpha, which is a transcription factor required for normal granulocyte differentiation. C/EBP alpha is mutated in 6–10% of AMLs, and such cases tend to have M1 or M2 morphology, intermediate risk cytogenetics, and a favorable clinical outcome.

IDH1/IDH2 mutations

Mutations in *IDH1* and *IDH2* result in loss of their normal enzyme function and create a novel ability of the enzymes to convert α-ketoglutarate into 2-hydroxyglutarate, a possible oncogenic metabolite. Mutations in *IDH1*/*IDH2* are found in 15–20% of AMLs and seem to be associated with a worse outcome, especially in patients with otherwise favorable *NPM1* mutations.

Other non-random mutations in AML

Recently, the Cancer Genome Atlas Research Network performed whole exome sequencing on 200 cases of AML and found each case had, on average 13 mutations of which 8 were random while 5 were in genes recurrently mutated in AML [11]. The most commonly mutated genes were *FLT3*, *NPM1*, *DNMT3A*, *IDH2*, *TET2*, *RUNX1*, *TP53*, *NRAS*, *CEBPA*, and *WT1*.

Gene and microRNA expression Abnormal levels of expression of a number of single genes, including *BAALC*, *EV1*, *ERG*, and *MN1* has been reported in AML and linked with prognosis. Genome-wide expression profiling has identified distinct clusters of AML cases with distinct outcomes. Aberrant expression of multiple microRNAs has also been reported in AML. These studies, however, have not yet impacted standard clinical practice.

Classification

The WHO has proposed a classification schema for AML that includes as subgroups AML with the most common recurrent cytogenetic abnormalities, AMLs that evolve from MDS, AMLs that are therapy related, and, for those that do not fit into the first three categories, AML organized according to morphology (see Table 50.1) [12]. Although comprehensive, this classification system is not organized according to prognosis and therefore is not widely used in the development of treatment guidelines. Two decades ago, the Southwest Oncology Group (SWOG) and the UK Medical Research Council (MRC) each developed and adopted classification schemas that were based solely on cytogenetics [13,14]. The two systems, although not identical, were very similar, and defined the favorable risk group as t(15;17), t(8;21), and inv(16); the unfavorable group as abn(3q), del(5q)/−5, del(7q)/−7, t(6;9), and complex (≥3 unrelated abnormalities). All other cases were defined as intermediate. The MRC has since revised their schema slightly (see Table 50.2).

Although broadly used, these schemas do not include the non-cytogenetic mutational analyses that have more recently become available. More recently, classification systems that combine cytogenetics and molecular studies and which are based on treatment outcome have been developed. One widely used schema has been published by the European LeukemiaNet (ELN) (Table 50.3) [15]. Briefly, the favorable risk group includes the core binding factor AMLs t(8;21) and inv(16), and also those cases with normal cytogenetics and mutated *CEBPA*, or mutated *NPM1* and wild-type *FLT3*. The intermediate-1 category includes all those with a normal karyotype except those defined as favorable, and the intermediate-2 category includes all those with cytogenetic abnormalities not specifically defined as favorable or unfavorable. The unfavorable group includes those with inv(3) or t(3;3), t(6;9), t(v;11), or *MLL* rearrangements, −5 or del(5q), −7, abnl(17p), and complex karyotype. Figure 50.1 illustrates the overall survival of patients with AML according to ELN risk categories [16]. Others have reported similar results[17]. More complex systems that integrate additional mutations, and in some cases gene expression markers, have been published but have not yet gained wide usage.

Table 50.2 Cytogenetic classification of AML

Risk status[a]	SWOG [13]	MRC (1998) [14]	MRC (2010) [14]
Favorable	t(15;17), t(8;21), inv(16)/t(16;16)/ del(16q)	t(15;17), t(8;21), inv(16)/t(16;16)/ del(16q)	t(15;17)(q22;q21), t(8;21) (q22;q22), inv(16) (p13q22)/t(16;16)(p13;q22)
Intermediate	Normal, +8, +6, –Y, del(12p)	Normal, 11q23 abn, +8, del(9q), del(7q), +21, +22, all others	Abnormalities not classified as favorable or unfavorable
Unfavorable	abn(3q), del(5q)/–5, –7/ del(7q), t(6;9), t(9;22), 9q, 11q, 20q, 21q, 17p, complex (≥3 unrelated abnormalities)	abn(3q), del(5q)/–5, –7, complex (≥5 unrelated abnormalities)	abn(3q) [excluding t(3;5) (q21–25;q31–35)], inv(3) (q21q26)/t(3;3)(q21;q26), add(5q)/ del(5q)/–5, add(7q)/del(7q)/–7, t(6;11) (q27;q23), t(10;11) (p11–13;q23), t(11q23) [excluding t(9;11) (p21–22;q23) and t(11;19) (q23;p13)],t(9;22) (q34;q11), –17/ abn(17p), complex (≥4 unrelated abnormalities)
Unknown	All other abnormalities	Category not recognized	Category not recognized

Clinical and laboratory presentation

The usual presenting symptoms of AML relate to decreased production of normal blood cells. Most patients are anemic at presentation and often complain of decreased exercise tolerance, fatigue, and headache. Thrombocytopenia is usually present and approximately one-third of patients note easy bruising, bleeding gums, or epistaxis. One-third of patients will present with significant infections, usually of bacterial origin. In addition to symptoms related to various cytopenias, diffuse bone pain and/or tenderness is noted by approximately 25% of patients. Leukemic infiltrates can give rise to chloromas, gingival hyperplasia, and leukemia cutis.

On presentation, most patients have a normochromic, normocytic anemia and are thrombocytopenic with 50% having platelet counts less than 50,000/mm^3. Most patients are granulocytopenic but the total WBC count is more variable, with 25% having a WBC count above 50,000/mm^3, 25% below 5000/mm^3, and the remainder in-between. The bone marrow is usually hypercellular and, by definition, must have >20% blasts to be considered AML as opposed to MDS. Patients with APL usually have prolonged partial thromboplastin and prothrombin times, reduced fibrinogen, and other evidence of disseminated intravascular coagulation. Blood chemistries in patients with newly diagnosed AML are usually normal, but some patients with very aggressive disease may have evidence of tumor lysis syndrome. Lumbar puncture will show unsuspected central nervous system (CNS) involvement with AML in 2% of cases. However, a randomized trial showed no advantage for CNS surveillance or prophylaxis in adult AML [18].

Non-transplant approach to treatment

Remission induction

If untreated, AML is usually a rapidly fatal disease, with death from bleeding or infection occurring within several months. Guidelines for initial therapy in AML often provide separate suggestions for patients younger or older than an arbitrary cutoff, usually around 60 years, based on the implicit assumption that older patients are less able to tolerate intensive induction therapy. Recent studies have examined the likelihood of early mortality after induction therapy and have found that although age plays a role, other factors, including performance status and prior treatment, make a larger contribution. hence the choice of initial induction therapy should be based on whether the patient is eligible for intensive therapy or not, and not on age per se. In general, intensive therapy is appropriate for patients at least up to age 75 years if they have a good performance status and limited comorbidities. The goal of induction therapy is the achievement of a morphologic complete remission (CR), which, according to the International Working Group recommendations, is defined as <5% marrow blasts with recovery of peripheral counts to an absolute neutrophil count of >1000/mm^3 and a platelet count of >100,000/mm^3 [19]. Standard induction therapy for patients up to age 65 years consists of an anthracycline such as daunorubicin, 60–90 mg/m^2/day for 3 days, or idarubicin, 12 mg/m^2/day for 3 days, combined with cytarabine given at a dose of 100–200 mg/m^2/day by bolus or continuous infusion for 7 days [20,21]. Patients above age 65 years with good performance status are generally treated similarly, but there is no advantage for anthracycline doses above 45–60 mg/m^2/day in this age group. With this approach, 65–80% of patients will achieve an initial remission. Approximately 5% of patients die of bleeding or infection during the period of pancytopenia, and approximately 20% will have persistent leukemia following intensive induction therapy. Numerous variations on the standard “3 + 7” theme have been studied, including other doses and schedules of anthracycline and cytarabine, the addition of other chemotherapeutic agents to the standard two-drug regimen, or the use of hematopoietic growth factors simultaneous with or following chemotherapy. None of these have convincingly improved outcome, although there are some recent encouraging results with the addition of gemtuzumab ozogamicin.

Postremission chemotherapy

If patients are given only induction chemotherapy, AML will inevitably recur, usually within 4–6 months. Therefore, some form of postremission therapy is required. Most contemporary protocols include repetitive cycles of high-dose cytarabine-containing consolidation chemotherapy for patients under age 65 years who are not transplanted in first remission. Among the more widely used regimens are those reported by the Cancer and Leukemia Group B [22], which consists of four cycles of cytarabine 3g/m^2 twice daily on days 1, 3, and 5, and the regimen of the MRC consisting of one cycle of standard “3 + 7” followed by a cycle of “MACE” chemotherapy that includes amsacrine, cytarabine, and etoposide, and a final cycle of high-dose cytarabine plus mitoxantrone [23]. Recently, consolidation with intermediate-dose cytarabine (1g/m^2 every 12 hours on days 1–6) was compared with high-dose cytarabine (3g/m^2 every 12 hours on days 1–6) and no advantage was seen with the higher dose regimen [24]. With standard consolidation therapy, approximately 35–40% of patients who achieve an initial CR can be expected to be alive in continuous first remission at 5 years from original diagnosis. As previously mentioned, the outcome of conventional chemotherapy is heavily influenced by cytogenetic and molecular markers of the disease.

Chemotherapy for recurrent AML

Patients who relapse after an initial remission achieve a second CR 30–50% of the time. Unfortunately, the median duration of second remission is generally short, averaging 6 months, and very few patients will remain in remission if treated only with chemotherapy. Mortality rates associated with reinduction have been 15–25%. Prognostic factors that have been consistently associated with an improved chance of achieving a second remission include younger age, favorable cytogenetic risk group and longer duration of first remission [25]. The choice of reinduction chemotherapy depends on the prior treatment received by the patient and also patient age and health. Younger patients with an initial remission of 6 months or longer are typically treated with a regimen containing an anthracycline plus high-dose cytarabine. The addition of cyclosporine to reverse multi-drug resistance was shown to be efficacious in one randomized trial [26]. For patients with shorter first remissions, alternative therapies, such as clofarabine-containing combinations, should be considered. A considerable number of agents are being studied for recurrent AML, including *FLT3* inhibitors, farnesyl transferase inhibitors, histone deacetylase inhibitors, antiangiogenic agents, and inducers of apoptosis, among others.

The special case of APL

Because APL is uniquely sensitivity to ATRA, arsenic trioxide, and anthracyclines, its treatment differs from that of other AML subtypes [27]. Initial induction therapy generally includes ATRA plus an anthracycline, with or without the addition of other chemotherapy. Complete response rates of 90–95% can be expected with such therapy. Induction failures are usually due to early bleeding events or, less commonly, drug resistance. Patients typically receive several cycles of consolidation therapy including ATRA and an anthracycline. A large prospective randomized trial showed that the further inclusion of two cycles of arsenic trioxide as consolidation therapy significantly improved event-free and overall survival [28]. In previous studies, maintenance with ATRA has also been found to be beneficial. With modern chemotherapy, at least 75% of patients with APL can be expected to be alive and disease free 3 years or more after diagnosis. Both age and WBC count at diagnosis are of prognostic importance, with the best results seen in patients aged less than 50 years presenting with a WBC count of less than 10,000/mm^3. The choice of treatment for recurrent APL depends on the specific clinical situation. Arsenic trioxide is the agent of choice for those patients who have not previously been exposed to the drug; in that setting, second CRs can be expected in 85% of cases. Patients resistant to ATRA and arsenic may respond to gemtuzumab ozogamicin.

Hematopoietic cell transplantation

Indications for allogeneic HCT in AML

Primary induction failure

Patients who fail primary induction chemotherapy have essentially no chance of cure with alternative chemotherapies, but several studies have shown that long-term survival is possible if such patients undergo allogeneic transplantation from an HLA-matched sibling. For example, the European Group for Blood and Marrow Transplantation (EBMT) reported 21% 3-year disease-free survival in a group of 88 patients with AML who were transplanted after failing at least two cycles of induction chemotherapy [29]. Similar results have been published by others [30]. Because of the time required to perform a search, there is less experience with the use of unrelated donors for primary induction failure, but the limited data available demonstrate that cure is possible in approximately 20% of cases [31]. These results emphasize the importance of HLA typing patients and family members shortly after the diagnosis of AML so that valuable time is not lost in identifying suitable donors should remission attempts fail.

How quickly patients should be taken to transplant is often determined by logistical issues. However, most experts would suggest that there is little to be gained by persisting with standard chemotherapy if a CR is not achieved after two cycles of conventional dose induction, or one cycle containing high-dose cytarabine [32].

First remission

Multiple prospective studies have since been conducted in which patients who had achieved an initial CR were assigned to an allogeneic transplant if they had a matched sibling, or to either consolidation chemotherapy or autologous transplantation if they lacked a donor. Several meta-analyses have been conducted reviewing all such studies, provided that the studies reported overall survival, and were analyzed in an intent-to-treat manner. The meta-analyses found an overall survival advantage to allogeneic transplantation in first remission, compared with either chemotherapy or autologous transplantation [33,34]. If analyzed by cytogenetic risk group, this advantage was greatest for patients with unfavorable risk cytogenetics, was still present in those with intermediate risk disease, but was not present in those with favorable risk disease (see Figure 50.2). Based on these studies, allogeneic transplantation is not generally recommended for patients with favorable risk cytogenetics in first CR. There are, however, data suggesting that among the good-risk group, some subgroups do less well with standard chemotherapy, including those with mutations in *KIT* and those with treatment-related AML. Whether these subgroups do better with allogeneic HCT in first CR is unknown.

	No. of patients			
	Donor group	No-Donor group	No. of trails	HR (95% CI)
Overall survival benefit by cytogenetic risk				
Good-risk AML	188	359	10	1.07 (0.83–1.38)
Intermediate-risk AML	864	1635	14	0.83 (0.74–0.93)
Poor-risk AML	226	366	14	0.73 (0.59–0.90)

Test for heterogeneity: $\chi^2_2 = 5.29$; $P = 0.07$; $I^2 = 62.2\%$

Figure 50.2 Overall survival benefit of allogeneic HCT for AML in first CR by cytogenetic risk group. Source: Koreth et al. 2009 [34]. Reproduced with permission of the American Medical Association.

As noted earlier, patients without clonal cytogenetic abnormalities were previously included in the cytogenetically defined intermediate risk group, but more recent molecular studies have been able to segregate these patients into those with a more favorable outcome with chemotherapy (*CEBPA* mutant, or *NPM1* mutant without *FLT3* mutations) and those with a less favorable outcome (all others). Schlenk et al. published the results of a prospective study involving 872 patients with cytogenetically normal AML in first remission [35]. Those with a matched sibling were allocated to transplantation. Among those with mutant *NPM1* and wild-type *FLT3*, the outcomes were similar whether one had a matched sibling or not [hazard ratio (HR) for relapse or death during CR 0.92, 95% confidence interval (CI) 0.47–1.81], whereas there was a clear benefit for having a donor and proceeding to transplantation for all others (HR 0.61, 95% CI 0.40–0.94) (Figure 50.3).

While the benefit of matched related donor HCT for patients with intermediate and high-risk disease (using the ELN categorization) seems clear, only about one-third of all patients will have a matched relative to serve as donor. The development of unrelated donor registries makes it possible to find matched unrelated donors for many patients. Results from single centers, in addition to registry data, suggest that outcomes of transplantation for AML in first remission using matched related and matched unrelated donors are similar [36,37]. The Center for International Blood and Marrow Transplant Research (CIBMTR) recently compared the outcomes for 600 recipients of matched related HCT with those for 1156 recipients of matched unrelated HCT for AML, about half of whom were in first remission. Survival at 3 years was 39% in matched related recipients compared with 37% for unrelated recipients. In multivariate analysis, these results were indistinguishable [relative risk (RR) = 1.06] (see Figure 50.4) [37].

The National Marrow Donor Program estimates that it is now possible to identify an 8/8 allele matched donor for 45–70% of Caucasians, depending on their country of origin, 29–38% of Hispanics, and 12–20% of African-Americans. Compared with outcomes using a matched related donor, the use of a single antigen-mismatched donor increases the risk of mortality (HR 1.36, 1.19, 1.16, and 1.48 for mismatching at HLA-A, -B, -C and -DR, respectively) [38]. Results with partially matched double cord transplants have recently been compared with the outcomes of matched related and matched unrelated transplants in a study from Seattle and Minnesota [39]. Although transplant-related mortality was higher with double cord transplants, relapse rates were lower and overall survival was equivalent in all three groups. The studies showing relative equivalence of matched related, matched unrelated, and double cord blood transplants argue that the indications for transplantation should generally be the same with all three donor sources. However, these were retrospective comparisons and patient selection bias could have influenced these results. A prospective study has recently been published by the German–Austrian Group (AMLHD98A) in which patients with high-risk AML, defined either by cytogenetics or by failure to achieve a CR with induction therapy, were assigned to transplantation. The 5-year overall survival for those who were not transplanted was 6.5%, compared with 25.1% for those undergoing transplant. There was no difference in outcomes between the 62 recipients of matched related HCT and the 89 recipients of matched unrelated donor HCT [40].

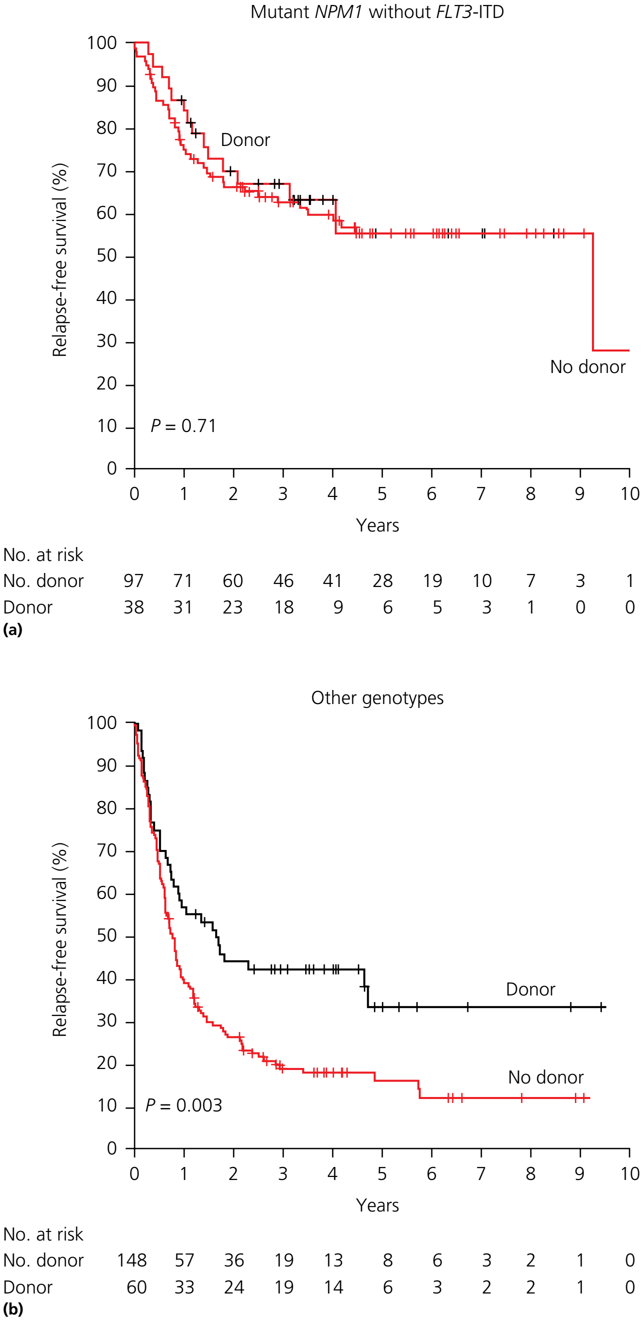

Figure 50.3 Relapse-free survival among patients with AML who achieved a first CR according to the availability of an HLA-matched related donor. Source: Schlenk et al. 2008 [35]. Reproduced with permission of the Massachusetts Medical Society.

The role of allogeneic transplantation for healthy but older patients with AML in first remission is less clear. There are inherent problems in attempting to conduct a prospective trial in this population, including a relative lack of healthy donors, and also patient and physician bias. Accordingly, no sufficiently sized prospective trial comparing transplantation with further chemotherapy has yet been reported. The Japanese National Cancer Center retrospectively examined the outcome of 1036 patients aged 50–70 years with AML who achieved a first CR and were then treated with either allogeneic HCT (n = 152) or chemotherapy (n = 884). Both relapse-free and overall survival were significantly improved in the HCT group, but of course patient selection bias could have influenced the results [41].

Second or subsequent remission

If patients are not transplanted in first remission, the general consensus is that they should receive an allogeneic transplant in second CR if possible. Occasionally, chemotherapy-induced second remissions can be prolonged, but this is a relatively rare event restricted to patients with favorable risk cytogenetics and a long first remission. Generally, second remissions are short, averaging 6–9 months. Breems et al. developed a prognostic index for overall survival in patients with AML in first relapse and identified the duration of first remission, age, and cytogenetic risk group as the three most important factors predictive of longer survival. However, in this retrospective analysis, no matter what the risk category was, improved survival was seen in those patients who were able to receive a matched related allogeneic transplant [25].

Patients with AML in second CR (CR2) lacking matched siblings are candidates for either matched unrelated or autologous transplantation. The CIBMTR database reports 5-year survivals of 42 ± 2% for unrelated donor transplantation for AML in CR2 and 40 ± 3% with autologous transplantation [42]. The decision to pursue an unrelated versus an autologous transplant for the patients represented in the registry was undoubtedly affected by multiple considerations that could introduce considerable bias into any comparison between groups. No prospective randomized trial comparing autografting with unrelated donor transplants for AML in CR2 has been published. In an effort to reduce possible bias, single-institution and registry comparisons have been performed using either matched-pair analyses or proportional hazards regression adjusted for differences in prognostic variables [43,44]. These studies consistently showed decreased relapse rates but increased non-relapse mortality with unrelated transplantation. In none of the studies was the difference in leukemia-free survival statistically significantly different. None of these studies were designed to address whether particular subsets of patients might benefit from one approach or the other, but the improved control of leukemia with unrelated transplantation but increased non-relapse mortality suggests that unrelated transplantation might be favored in situations where there is a higher risk of relapse and a lower risk of toxicity (younger patients with shorter first remissions) whereas autologous transplantation might be favored in opposite settings (older patients with longer first remissions).

Untreated first relapse

Whether patients with AML in untreated first relapse who are transplant candidates should go directly to transplant or should first undergo chemotherapy in an attempt to induce a second remission prior to transplant is an unanswered question. Frequently the issue is moot, since non-medical issues including insurance clearance and transfer to a transplant center often require time and do not permit rapid initiation of the transplant procedure. However, with improving technologies applied to the detection of minimal residual disease, it is likely that in the near future an increasing number of patients will be diagnosed with incipient relapse, allowing greater lead time and thus making transplantation in untreated first relapse a more feasible approach.

To date, there have been only a limited number of published studies describing the outcome of transplantation in untreated first relapse. Studies from Seattle and elsewhere report survival rates at 5+ years of approximately 30% for matched related donor transplants for AML in untreated first relapse [45,46]. Only limited data exist on the outcome of allogeneic HCT for AML in untreated first relapse using other sources of marrow. A single study of autologous transplantation described 38 patients whose marrow had been stored in first remission who underwent autologous HCT at first relapse using a conditioning regimen of busulfan plus cyclophosphamide and post-transplant received IL-2 with or without lymphokine-activated killer cells [47]. Eight of the 38 patients were alive in remission at the time of the report. Because of the time required to identify and schedule an unrelated donor, there are almost no reports of unrelated donor transplants for AML in untreated first relapse, but the few reported cases suggest an outcome not markedly different from that seen with matched related donors [48].

Although the outcomes for transplantation in untreated first relapse are apparently not as favorable as outcomes in second remission, it should be remembered that reinduction attempts are successful in, at best, 50% of cases, and those who fail reinduction either never are transplanted or are transplanted in refractory relapse. A thought experiment conducted using available data suggests that among 100 patients subjected to reinduction, 50 would achieve a CR2 and if every one of those patients were transplanted, approximately 20 would be cured (50 × 0.40). Among the other 50, 15–20% would die or suffer complications during reinduction that would preclude subsequent transplant, and of the remaining 30, perhaps three (10%) would be cured. Hence this approach would yield 23 cured patients, which is less than the 30% cure rate reported for transplantation in untreated first relapse. Of course, considerable selection bias may have influenced those patients transplanted in untreated first relapse. In limited allogeneic experience of HCT in untreated first relapse, there was a trend towards better outcome in those who developed graft-versus-host disease (GVHD) and in those with less disease burden at the time of transplant, but no effect on the duration of first remission, whereas in the autologous experience, both increasing tumor burden and shorter first remission negatively impacted outcome. Available data are very limited, but based on what is currently known, patients with matched siblings or previously stored autologous stem cells might be considered for transplant in untreated first relapse if disease recurrence is detected at an early stage and logistical issues do not present a roadblock.

Refractory relapse

Various definitions of the term "refractory relapse" exist, making simple statements about treatment outcome for such patients based on published studies difficult. A strict and relatively unambiguous definition of patients in refractory relapse includes only those who have failed their last reinduction attempt. Although a second reinduction using an alternative regimen is sometimes tried, such efforts are rarely beneficial. For example, based on data from a retrospective study conducted by investigators at the M.D. Anderson Cancer Center, the likelihood of achieving a CR was <1% following administration of chemotherapy to patients whose AML failed to respond to the last initial reinduction attempt [49]. Results with transplantation in this strictly defined group of patients are also relatively poor. With matched sibling transplants, disease-free survival at 3 years or more was seen in only approximately 10% of such patients [50]. Similar results have been reported using unrelated donors, with 7% 5-year disease-free survival seen in 81 patients transplanted for refractory relapse [31]. Among those transplanted in refractory relapse, the results are marginally better if patients have a lower leukemia burden without circulating blasts. This has led to the approach of administering intensive chemotherapy in an attempt to clear circulating leukemic blasts prior to initiating a transplant procedure [51]. Whether these attempts at reducing tumor burden change the ultimate outcome of transplantation remains unknown.

Many reports use a less stringent definition of refractory relapse or have lumped together primary induction failure, untreated relapse, and refractory relapse. The CIBMTR reported on 1673 AML patients combining these different forms of relapse [52]. Survival 3 years after transplant was 19%; those with shorter first remissions, circulating blasts, poor performance status, poor risk cytogenetics, and receiving transplant from donors other than HLA-matched siblings not surprisingly did worse.

Indications for autologous HCT in AML

First remission

The comparative utility of autologous HCT versus chemotherapy for patients with AML in CR1 has been the subject of numerous randomized controlled trials. Between 1989 and 1998, six prospective randomized trials were conducted in which patients with AML in first remission were randomized to further chemotherapy or autologous HCT with bone marrow as the stem-cell source. A meta-analysis of these studies found that transplantation was associated with improved disease-free survival, but no improvement in overall survival [53]. In the following decade, three similar studies were conducted, but using peripheral blood rather than marrow as the source of autologous stem cells. The outcomes of those three trials were similar to the previous six, and a subsequent meta-analysis of all trials published through 2010 comparing autologous HCT (using either marrow or peripheral blood) with further chemotherapy concluded that autologous HCT was associated with improved disease-free survival without impacting overall survival [54].

Second or subsequent remission

As noted earlier, registry data report a 40 ± 3% disease-free survival at 5 years for patients with AML in second remission treated with autologous transplantation. These results appear very similar to those achieved with either matched related or matched unrelated donor transplantation, but patient selection bias could play a major role affecting these outcomes. These have been no prospective randomized trials comparing autologous with allogeneic transplantation for AML in second remission, so there are few objective data to guide the physician's choice.

HCT-specific issues

Preparative regimens

The general topic of transplant preparative regimens is reviewed in Chapter 20. The initial preparative regimens used for transplantation in AML were myeloablative, but more recently a large number of regimens of less intensity have been developed. In an effort to facilitate discussion on the topic, the CIBMTR has defined regimens on the basis of what would happen without transplantation of stem cells: (1) myeloablative (myeloid recovery is not expected), (2) reduced intensity (recovery will occur but only after a prolonged period), and (3) non-myeloablative (rapid and uneventful recovery is expected) [55]. A limited number of trials have explored the question of the optimal myeloablative regimen for patients with AML undergoing matched sibling HCT [56]. Two prospective randomized trials studied the issue of total body irradiation (TBI) dose when combined with a set dose of cyclophosphamide (Cy) in patients with AML in CR1. One study showed that 12 Gy of fractionated TBI was superior to 10Gy of TBI delivered as a single dose [57], whereas a second trial found that relapse rates were lower but non-relapse mortality was higher when the dose of fractionated irradiation was increased from 12 to 15.75Gy [56,58]. A single randomized trial explored the form of chemotherapy in combination with TBI and found melphalan and Cy to be equivalent [59]. A further randomized trial compared Cy plus TBI with busulfan (BU) plus Cy and found a significantly lower relapse rate with the TBI-containing regimen resulting in improved disease-free survival [60]. Subsequent retrospective registry data comparing 223 patients with AML in first CR transplanted using a Cy plus TBI regimen with a similar number of patients treated with BU plus Cy found relative equivalence of the two regimens [61]. Reasons for the discrepancy between the randomized trial outcome and registry data are not obvious.

As noted above, a large number of reduced-intensity and non-myeloablative regimens for allogeneic transplantation for AML have been developed. The initial impetus for their formation was the hope that benefits of reduced toxicity would at least balance the cost of increased relapse rates, especially in older patients and those with comorbidities. Despite the extensive literature on the topic, no large prospective randomized trials have been published to date. However, there have been a number of retrospective registry comparisons. Among the largest are reports from the EBMT and the CIBMTR. The EBMT compared 401 AML patients receiving reduced-intensity regimens with 1154 recipients of myeloablative transplants and found less relapse with myeloablative regimens, but lower non-relapse mortality in patients aged over 50 years [62]. These results favor higher intensity regimens in younger, but not older, patients. The study from the CIBMTR reached somewhat similar conclusions when examining the outcomes for 3731 recipients of myeloablative and 1448 recipients of reduced-intensity or non-myeloablative transplants [63]. BMTCTN 0901 was a prospective randomized trial comparing myeloablative to reduced intensity conditioning in the treatment of adults with AML or myelodysplasia. The study was recently stopped by the Data Safety Monitoring Board because of concern for an increased failure rate in the reduced-intensity arm.

Only a single, small randomized trial has compared high-dose preparative regimens prior to autologous transplantation and found relative equivalence between Cy plus TBI and BU plus Cy [61]. Registry data since confirmed the relative equivalence of Cy plus TBI and BU plus Cy for patients with AML undergoing autologous HCT in first CR [64].

Although a number of alternative and novel approaches to high-dose preparative regimen development have been reported, no randomized trials other than those noted above have been published, and insufficient numbers of patients have been treated with any one alternative to allow for retrospective comparisons that would be sufficiently meaningful to alter standard therapy.

Source of hematopoietic stem cells

The source of hematopoietic stem cells for transplantation can be defined both according to the relationship of the donor and recipient (autologous, matched sibling donor, matched unrelated donor) and according to their anatomic site (bone marrow, peripheral blood, umbilical cord blood). The broad topics of stem-cell source are dealt with in greater detail in Chapters 36–45. The following discussion is limited to specific issues of stem-cell source selection in the treatment of AML.

Sibling versus autologous versus unrelated donors

The choice of matched sibling versus autologous versus unrelated donor transplant is, of course, driven by the clinical state of the patient and the availability of hematopoietic stem cells. The only clinical situation in which there are prospective data to guide the choice is in first CR. As noted above, two large meta-analyses have been performed addressing this question and are in general agreement that allogeneic transplantation offers a survival advantage in this setting, particularly in patients with intermediate and high-risk disease, whereas with autologous transplantation, although there may be some gain in disease-free survival, no overall survival benefit was evident [33,34]. A number of single-institution and registry data support the contention that survival following matched related and matched unrelated transplants is now approximately the same [36,37]. Hence indications should not differ between the two. Also, other data suggest, at least for patients aged <50 years, that results with double cord blood transplants are similar to those seen with matched related and matched unrelated transplants [39].

Lack of prospective randomized trials make the choice of donor for patients with more advanced disease less clear. General practice is to use a matched sibling whenever one is available. Retrospective comparisons of autologous transplantation with unrelated donor transplants for patients with AML in second remission have demonstrated similar outcomes [43,44], but such comparisons are inherently limited by possible treatment selection bias, and most experts would favor matched unrelated transplants, particularly for younger patients, reserving autologous transplantation for those who are older, have significant comorbidities, or have incompletely matched donors.

Stem-cell source for autologous transplantation

Purging

Initial studies of autologous transplantation for AML utilized unmanipulated bone marrow. An obvious concern with autologous transplantation is that clonogenic leukemia cells might be reinfused with the remission marrow, a possibility formally demonstrated by Brenner et al. using gene marking of remission marrow [65]. Accordingly, various techniques were developed that in animal models are capable of eliminating clonogenic tumor cells from marrow mixtures without causing obvious harm to the marrow itself (see Chapter 41 for a thorough review). Subsequently, numerous phase I/II trials exploring these techniques were conducted. The most widely used approach was treatment of marrow in vitro with the potent alkylating agent 4-hydroperoxycyclophosphamide (4-HC). A retrospective analysis from the Autologous Blood and Marrow Transplant Registry (ABMTR) reviewed 294 patients with AML who underwent autologous HCT in first remission. In a multivariate analysis, use of 4HC was associated with improved disease-free survival at 3 years (56% with purging vs. 31% without) [66]. Despite encouraging retrospective data, no prospective randomized results have been published, hence this approach is not approved by the US Food and Drug Administration (FDA), and the drug is not currently commercially available.

Peripheral blood versus bone marrow

Autologous peripheral blood hematopoietic cells (PBHCs) collected following chemotherapy and growth factor administration provide an alternative to autologous bone marrow as a source of stem cells for autografting. Use of PBHCs is clearly associated with faster engraftment and reduced early morbidity after autografting, and therefore has become popular. However, the effects of choosing peripheral blood over bone marrow on overall survival are less clear. In fact, Gorin et al., after analyzing 2165 patients who received autografts for AML in first remission, found that the relapse rates were significantly higher with peripheral blood as opposed to marrow, resulting in inferior leukemia-free survival [67]. They further showed that those patients who received the highest CD34$^+$ cell doses, although engrafting faster, had the highest relapse rates [68].

A question of interest with the use of unpurged PBHCs is whether more intensive therapy prior to collection of hematopoietic stem cells might improve the purity of the stem-cell yield, reduce tumor burden in the patient, and thereby decrease subsequent relapse rates. Tallman et al. conducted a retrospective analysis of registry data and reported that the risk of relapse and treatment failure was significantly lower among patients receiving consolidation chemotherapy prior to hematopoietic stem-cell collection than in patients receiving no consolidation [69]. They did not find a difference between groups receiving high-dose cytarabine consolidation regimens and those receiving standard dose regimens. Because of the retrospective nature of the analysis, it is difficult to know if the observed effect was at least in part due to drop-out of high-risk patients during the consolidation phase. Nonetheless, most current trials of autologous transplantation include at least one, and often several, cycles of consolidation prior to hematopoietic stem-cell harvest and transplant.

Hematopoietic stem-cell source for allografting

Bone marrow cell dose

Numerous studies have now demonstrated that bone marrow cell dose is closely linked with clinical outcome after both matched sibling and unrelated donor transplants for AML. This association was initially shown following unrelated donor transplantation for AML where a marrow cell dose of $>3.0 \times 10^8$ nucleated cells per kilogram was found to be associated with a superior outcome [70]. Subsequently, a similar association has been found following matched sibling transplantation. For example, Rocha et al. showed that among 572 patients undergoing allogeneic bone marrow transplantation for AML in CR1, both relapse and non-relapse mortality were reduced in those patients receiving a nucleated cell dose of $> 2.6 \times 10^8$ resulting in superior leukemia-free survival for this group [71]. Similar results have been published by others using the number of CD34$^+$ marrow cells as the variable [72]. The explanation for the association of higher marrow cell dose with improved clinical outcome is not clear, but the association is maintained after accounting in multivariate analysis for patient age, gender, and other obvious potentially confounding factors.

Bone marrow versus peripheral blood

The rapid engraftment seen with the use of autologous growth factor-mobilized PBHCs encouraged pilot studies of the use of allogeneic PBHCs. These pilot studies demonstrated rapid granulocyte and platelet engraftment and, despite a far higher mature T-cell content than present in marrow, no obvious increase in acute GVHD with the use of allogeneic PBHCs. Based on these encouraging pilot studies, a number of prospective randomized trials were conducted comparing marrow with growth factor-mobilized PBHCs as the source of stem cells for matched sibling transplantation following standard high-dose preparative regimens. A meta-analysis of nine randomized trials enrolling 1111 adult patients was conducted and reported [73]. Compared with marrow, use of PBHCs was associated with more rapid neutrophil ($p < 0.00001$) and platelet ($p < 0.00001$) engraftment. Whereas there was no difference in grade 2–4 acute GVHD (54% with PBHC versus 53% with marrow), there was an increase in extensive chronic GVHD (47% versus 31%) and overall chronic GVHD (68% versus 52%) with the use of PBHCs. Use of PBHCs was also associated with a decrease in relapse at 3 years, in both late- and early-stage patients (21% versus 27% overall). Non-relapse mortality was not different between the groups. When considering AML specifically, disease-free and overall survival in late-stage patients were significantly improved with the use of PBHCs (odds ratio = 0.45), whereas the results were less definitive for early-stage patients. A large retrospective registry analysis from the EBMT yielded similar findings [74]. Therefore, for patients with AML beyond first remission undergoing matched sibling transplantation following a high-dose preparative regimen, PBHCs are preferred, but for patients in first remission the choice is less clear.

Pilot studies of the use of PBHCs for matched unrelated transplantation have been conducted [75,76]. These studies were encouraged by the results seen with the use of PBHCs for matched sibling transplantation coupled with the observation that survival appears to be improved with higher CD34$^+$ cell doses following unrelated donor marrow transplantation. The results again showed rapid engraftment without intolerable GVHD. The Blood and Marrow Transplant Clinical Trials Network (BMT CTN) recently published the results of a large prospective randomized trial comparing peripheral blood with marrow for unrelated donor transplantation [77]. The overall 2-year survival was similar with the two stem-cell sources. Peripheral blood resulted in earlier engraftment and less graft failure, but was also associated with more chronic GVHD. This study was not restricted to AML, but given the results, the use of peripheral blood should probably be restricted to those patients in need of a rapid graft, or those at higher risk for graft rejection.

Umbilical cord blood

Umbilical cord blood as a source of hematopoietic stem cells for HCT is the topic of Chapter 39. The amount of information about the utility of cord blood transplants specifically as treatment for adults with AML is limited. An International Bone Marrow Transplant Registry (IBMTR) report compared the outcome of cord blood transplants in 140 adults with leukemia with that seen in recipients of unrelated HLA-matched ($n = 367$) or single antigen mismatched ($n = 83$) marrow [78]. Outcomes with cord blood and one-antigen mismatched marrow were very similar, but both were inferior to those seen with unrelated matched transplants. Results were not provided for specific leukemia subtypes or stages. The EBMT similarly compared outcomes of 98 adult recipients of cord blood transplants with acute leukemia with those seen in 584 recipients of unrelated bone marrow [79]. Multivariate analysis showed lower risks of GVHD with cord blood, but delayed engraftment. No significant differences in transplant-related mortality, relapse rates, or leukemia-free survival were seen between the groups. When the analysis was focused on subsets of patients, a trend towards improved 2-year leukemia-free survival was found for patients with AML treated with matched unrelated marrow compared with cord blood (42% versus 32%), whereas other subgroups appeared to benefit equally from cord blood and marrow. The registry nature of the IBMTR and EBMT reports makes it impossible to account for biases in patient selection, and no attempts were made to control for treatment regimen effects or differences in supportive care or other ancillary measures. Nonetheless, the reports suggest that the outcomes of unrelated bone marrow and cord blood transplants for adults with AML are sufficiently similar that, although one might prefer a matched unrelated donor, if none were available then a partially matched cord blood with sufficient cell dose is a reasonable substitute.

The majority of studies of adult cord blood transplants published so far utilized single cords as the source of stem cells and had a threshold for an acceptable cell dose (usually in the region of 2×10^7/kg), meaning that many possible candidates were not able to be transplanted because a cord of sufficient size could not be identified. The reason for the cell dose threshold is experience showing an increased incidence of graft rejection and poorer survival with lower cell doses. More recent experience combining multiple cords for a single transplant suggests that it might be possible to overcome this limitation. A study from Minnesota and Seattle showed that survival following ablative transplants for acute leukemia in remission are similar with matched sibling, matched unrelated. and double cord blood transplants (Figure 50.5) [39]. Use of cord blood was associated with a higher non-relapse mortality rate, but a lower risk of relapse.

GVHD prophylaxis

The general principles of GVHD prophylaxis are discussed in Chapters 81–84. As outlined in Chapter 81, the results of prospective randomized trials suggest that combinations of methotrexate and either cyclosporine or tacrolimus are the preferred pharmacologic approaches for prevention of GVHD in patients with AML undergoing transplants from matched siblings or matched unrelated donors following high-dose preparative regimens [80]. As discussed in Chapter 81, many alternatives to these regimens are

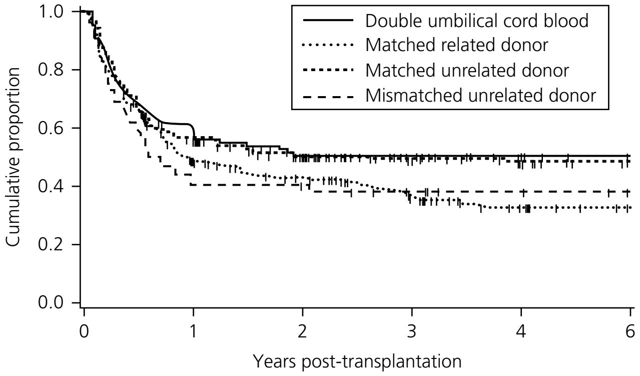

Figure 50.5 Leukemia-free survival among 536 patients by donor type. Source: Brunstein et al. 2010 [39]. Reproduced with permission of the American Society of Hematology.

currently being explored, including, for example, the substitution of sirolimus or mycophenolate mofetil for methotrexate, or the addition of antithymocyte globulin during the peri-transplant period. As yet, however, no prospective randomized trial has been reported showing superiority in terms of survival or disease-free survival of any alternative to the standard combination of methotrexate and a calcineurin inhibitor for GVHD prevention in the setting of high-dose preparative regimens.

As discussed in Chapter 82, removal of T cells from the donor stem cell inoculum as an alternative approach to GVHD prevention has been intensively studied. A variety of methods for T-cell removal have been developed and preparative regimens with increased immunosuppressive effects have been constructed that appear capable of preventing the increased incidence of graft rejection otherwise associated with the use of T-cell depletion. A single prospective randomized trial examining the effects of T-cell depletion on transplant outcome has been reported [81]. In that trial, 405 patients with a variety of hematologic malignancies undergoing matched unrelated marrow transplantation following high-dose preparative regimens were randomized to GVHD prevention with either T-cell depletion (using counterflow centrifugal elutriation or antibody T10B9 plus complement) plus cyclosporine versus pharmacologic immunosuppression with methotrexate and cyclosporine. Disease-free survival at 3 years was 27% with T-cell depletion versus 34% without ($p = 0.16$). Among the 101 patients with AML, disease-free survival at 3 years was 29% with T-cell depletion versus 33% without. This trial used marrow as the source of stem cells. More recently, availability of clinical-grade magnetic bead columns for cell separation have made it possible to accomplish a 4–5 log reduction in T cells from peripheral blood, thereby allowing a T-cell-depleted graft with a substantially higher number of $CR34^+$ cells than is possible using marrow. A recent paper compared the results of 44 patients with AML in CR1 or CR2 receiving T-cell-depleted peripheral blood grafts from matched siblings with 84 contemporaneous patients receiving matched sibling grafts followed by standard immunosuppressive therapy [82]. Overall survival at 3 years was 65% with standard immunosuppression versus 59% with T cell depletion. Chronic GVHD rates were 50% with standard immunosuppression and 19% with T cell depletion.

Measurement of minimal residual disease (MRD)

Measurement of MRD can potentially be useful to direct therapy after initial induction chemotherapy, to monitor response, or to select the best transplant approach. Two general methods have been developed to measure MRD in AML: those based on polymerase chain reaction (PCR) techniques, and those based on multidimensional flow cytometry (MFC) [83]. PCR-based approaches require that the leukemia have either a fusion gene, as in t(8;21) and inv(16) of *MLL* translocations, a mutation, as in *FLT3*, *NPM1*, or *CEBPA*, or that a gene is reliably overexpressed, such as *WT1*. The advantages of PCR-based approaches are their high sensitivity and relative ease of performance. However, only about 70% of AML populations will have fusion genes or mutations, and there are no generally agreed-upon standardized assays and cutoffs for RNA expression.

MFC takes advantage of the fact that AML blasts, in at least 90% of cases, express a combination of cell surface antigens and/or flow cytometric physical abnormalities that are absent in normal marrow cells. Depending on the number of monoclonal antibody combinations used in the assay and the skill and experience of the laboratory, this leukemic fingerprint can be used to detect as few as 0.01% leukemic cells in a remission marrow. Advantages of MFC are its wide applicability, rapid turnaround time, specificity, and ability to provide quantitative results.

Several groups have demonstrated that the level of MRD as measured by MFC after induction therapy predicts the chance of subsequent relapse, with progressively higher rates as the amount of MRD increases in cohorts from 0–0.01%, 0.01–0.1%, 0.1–1%, and above 1%. Most of these studies used marrow as the source of cells, but others suggest that peripheral blood can be used, although the cutoff levels for risk differ. How much measurement of postinduction MRD adds to information already available from pretreatment cytogenetics and molecular testing in deciding who should be transplanted in first CR is as yet uncertain. There are data suggesting that patients with favorable and intermediate risk disease by conventional standards who are MRD positive after induction have a very poor prognosis (15% relapse-free survival at 4 years). Similarly, patients with intermediate risk disease who are MRD free after induction may have an outcome almost as good as that for good-risk patients (60% relapse-free survival at 4 years). Confirmation of these results in larger studies is needed.

How these results should be used in developing a strategy for the optimal care of AML patients is uncertain. Although the presence of MRD after induction might be seen as an indication for transplantation, it also is the case that the presence of MRD at the time of transplant predicts a worse outcome. Studies at the Fred Hutchinson Cancer Research Center examined 253 consecutive patients with AML in first or second remission undergoing myeloablative HCT [84]. Among CR1 patients, the 3-year estimates of disease-free survival were 73 and 27% for patients without and with MRD respectively, and among CR2 patients, the corresponding figures were 71 and 47%. If MRD was modeled as a continuous linear variable, both the risk of death and the risk of relapse post-transplant increased as the level of MRD increased. Whether these outcomes can be improved by treating MRD-positive patients with alternative chemotherapies in the hope of rendering them MRD negative before proceeding to transplantation is unknown.

Relapse following HCT

Disease recurrence is a common cause of treatment failure following HCT, and is the topic of Chapter 70. In AML treated either with chemotherapy or with transplantation, most relapses will occur within 3 years of treatment [85]. Chemotherapy is sometimes successful in inducing a remission in patients who have relapsed after HCT. In one study of 95 patients with AML who relapsed after allogeneic HCT, the CR rate with subsequent chemotherapy was 34% [86]. Not surprisingly, CR rates were higher for those transplanted in remission (47% versus 18%) and for those who relapsed at longer intervals from transplant. Although subsequent remissions were possible, most of these were of limited duration, and without other therapies, long-term survival was seen in only 5% of patients.

By inducing an immunologic graft-versus-tumor effect, donor lymphocyte infusions (DLIs) can sometimes cause CRs in patients with a variety of malignancies who have relapsed after allogeneic HCT [87]. The EBMT retrospectively analyzed the data of 399 patients with AML in first hematologic relapse after HCT whose treatment did ($n = 171$) or did not ($n = 228$) include DLI [88]. Estimated survival at 2 years was 21 ± 3% for patients receiving DLI and 9 ± 2% for patients not receiving DLI. After adjusting for differences between the groups, better outcome was associated with younger age, relapse occurring more than 5 months after HCT, and use of DLI. Among DLI recipients, a lower tumor burden at the time of DLI (<35% marrow blasts), female gender, favorable cytogenetics, and remission at the time of DLI all were predictive of a better outcome. Survival at 2 years was 56 ± 10% for those given DLI while in chemotherapy-induced second CR.

Second allogeneic transplants have been explored as possible therapy for patients whose disease has recurred after an initial autologous transplant. Radich et al. reported on 59 patients, including 24 with AML, who were treated in this manner [89]. The 2-year disease-free survival was surprisingly good for the AML patients, at 46%. However, the majority of these patients were in the pediatric age group, received an autograft with busulfan/cyclophosphamide conditioning as the first transplant, and were able to be treated with a TBI-containing regimen with their allograft. Results in adults and those treated with TBI during their initial autograft were not as encouraging.

Second allogeneic transplantation after initial failure of allografting has also been studied. A survey conducted by the EBMT identified 170 patients with acute leukemia, including 85 with AML who underwent second allogeneic transplants after high-dose conditioning regimens for recurrent disease [90]. Both treatment-related mortality and the actuarial risk of relapse were high at 46 and 59%, respectively. Nonetheless, 25% leukemia-free survival at 5 years was reported. In multivariate analysis, a longer interval to relapse after first HCT, CR status at time of second HCT, use of TBI at second HCT, and development of acute GVHD at second HCT were associated with better outcomes. The leukemia-free survival was 52% at 3 years for those who relapsed more than 292 days after their first HCT and were in remission before receiving their second transplant. Whether one should use the same donor or switch to an alternative donor for the second transplant is unknown. Because in the above studies the development of GVHD was associated with improved tumor control, switching to an alternative donor if no GVHD developed with the first transplant is common practice.

Because of the high treatment-related mortality associated with second allogeneic transplants using high-dose regimens (46% overall, and 53% among those transplanted within 1 year of their first transplant), investigators have more recently been studying the use of reduced-intensity allogeneic transplants for patients whose disease has recurred after a first transplant. Baron et al. reported on 147 patients with hematologic malignancies, including 35 with AML or advanced MDS, who were treated with reduced-intensity conditioning and allogeneic transplantation after failing a conventional autograft or allograft [91]. The treatment-related mortality was 30%, and 44% of patients were alive at 3 years, including 29% of patients with AML or advanced MDS. Being in CR at the time of second transplant and developing chronic GVHD were both associated with improved survival.

The majority of patients included in these previous trials showed recurrence after an ablative preparative regimen. Schmid et al. examined the outcome of 263 AML patients whose disease had recurred after reduced-intensity conditioning [92]. The estimated 2-year overall survival from relapse was 14%. The only long-term survivors were those who achieved a CR with reinduction therapy and then went on to receive either DLI or a second allogeneic HCT.

HCT for APL

Because of the remarkable effectiveness of the inclusion of ATRA, and more recently arsenic trioxide, in the primary treatment of APL, there is no role of transplantation during first remission. Unfortunately, disease recurrence still occurs in approximately 10% of good-risk patients (those presenting with a WBC of <10,000/mm^3) and 25% of poor-risk patients. Second remissions can commonly be achieved with the use or arsenic trioxide, especially if patients have not previously taken the drug, with ATRA-containing regimens if the patients have relapsed off ATRA maintenance, or with the use of gemtuzumab ozogamicin. HCT is generally recommended as appropriate therapy for patients with APL who suffer an initial relapse. de Botton et al. reported on the outcome of therapy in 122 patients with APL whose disease recurred after initial treatment with an ATRA-containing regimen [93]. The 7-year event-free survival was 60.6% for those treated with an autograft, 52.2% for those treated with an allograft, and 30.4% for those treated without transplantation. Most of the patients treated with an autograft had marrow that was PCR negative for the t(15;17) at the time of hematopoietic stem-cell harvest and transplantation, a selection strategy based on previous reports that patients who are PCR positive at the time of autografting for APL have a very high chance of recurrence [94]. The report by de Botton et al., together with those of others, suggests that autologous transplantation is appropriate therapy for patients with APL who achieve a PCR-negative second remission, whereas allogeneic transplantation should be considered as appropriate salvage therapy for all others[95].

Conclusion

A major change from a decade ago is the integration of non-cytogenetic molecular abnormalities into the therapeutic decision-making process in AML. A proposed algorithm for patients with newly diagnosed disease is presented in Figure 50.6. With continued investigation into AML using gene expression arrays, mRNA patterning, and proteomics, this algorithm will likely change in the next decade, even if there are no advances in treatment modalities.

A second major change relevant to transplantation of AML over the last decade has been the continued development of reduced-intensity preparative regimens. These studies show that with appropriate pre- and post-transplant immunosuppression, engraftment can be reliably achieved and that treatment-related mortality can be substantially reduced. This is at the price of increased disease recurrence, but the development of reduced-intensity regimens offers new hope for older individuals who would otherwise not be candidates for transplantation and, importantly, provides a foundation on which to add additional therapies to the preparative regimen, such as radioimmunoconjugates specifically targeted at the tumor cell, or targeted small-molecule therapy during the early post-transplant period.

Continuing developments in the use of alternative donor transplants will further expand the potential application of allogeneic HCT for the treatment of AML. Perhaps the most interesting advance in this area over the past decade has been the emergence of cord blood transplants as a possible alternative for adults with AML. Outcomes of matched unrelated donor and cord blood transplantations for AML are approaching those seen with matched sibling donors. If this approach continues to show promise, it would address a major problem faced by the patient with high-risk AML who has achieved a first CR, does not have a suitably matched family member, and is at considerable risk for early relapse if a lengthy search for an unrelated donor is required.

Figure 50.6 Proposed algorithm for treatment of adults with newly diagnosed AML fit for aggressive therapy.

Although there have been important advances in HCT for AML over the last decade, there are also areas where the amount of progress has been disappointing. One such area is our inability to apply existing technologies systematically for the measurement of minimal residual disease to the decision-making process of who should be transplanted in first remission. It is also disappointing that we have been unable to develop broad clinically applicable methods to segregate the impressive power of the graft-versus-tumor effect from the toxicities of GVHD. These topics remain the focus of a great deal of research that, hopefully, will lead to real therapeutic advances in the near future.

CHAPTER 51

Hematopoietic Cell Transplantation for Childhood Acute Myeloid Leukemia

Introduction

Approaches used by various international study groups that include allogeneic hematopoietic cell transplantation (HCT) for childhood acute myeloid leukemia (AML) have shifted over time. Studies in the 1980s and 1990s that compared intensive chemotherapy with autologous HCT in complete remission (CR1) showed similar survival; however, recipients of matched family donor allogeneic HCT benefited from a graft-versus-leukemia (GVL) effect and achieved superior survival [1,2]. Analysis with improved risk classifiers showed that low-risk patients [i.e. t(8;21)] did well with chemotherapy alone [3], and high-risk patients did poorly with any approach [4]. A more clear survival advantage for matched related donor HCT in CR1 was shown in intermediate-risk patients [4]. This approach, however, is challenged by cooperative groups who only allow CR1 HCT in high-risk patients and others only in primary refractory or second remission patients, reasoning that salvage approaches can lead to similar overall survival (OS) [5].

These competing paradigms are being challenged due to several key advances. First, unrelated donor survival outcomes have improved dramatically, potentially suggesting that broader use of HCT could be beneficial [6]. Second, methods of minimal residual disease (MRD) measurement have been developed that more accurately predict outcome after chemotherapy, allowing better definition of low- and high-risk populations [7]. Third, specific cytogenetic abnormalities and gene mutations have been described that allow further refinement of risk, some associated with increased and others with decreased risk. Finally, small molecules and immunologic interventions targeting pathways in AML have been developed, and testing these interventions pre-/post-HCT or instead of HCT will further define indications for HCT in the coming years.

This chapter defines key AML biology and its relation to HCT outcomes, explains current approaches and indications, and introduces promising approaches that may impact outcomes in the near future.

Epidemiology/classification/molecular and cellular biology

AML is a heterogeneous and complex disease that is the culmination of interactions between genetic and epigenetic alterations in hematopoietic progenitors leading to dysregulation of multiple critical signal transduction pathways, resulting in accumulation of myeloid blasts and hematopoietic insufficiency. It is broadly accepted that AML evolves as a result of cooperation between two classes of genetic alterations. In this model, the initial transforming events are genomic alterations such as core binding factor (*CBF*) translocations and mixed lineage leukemia (*MLL*) translocations that are thought to arise in the hematopoietic stem/progenitor cells. Cells that are transformed by such mechanisms would have self-renewal properties, but lack proliferative potential and initially represent a minor clone in the hematopoietic progenitor population. These cells persist as a minor clone for extended periods until a time when a second "hit" confers proliferative properties, allowing expansion of this minor clone, leading to a leukemic phenotype. Recent technologic advances have allowed more complete interrogation of the AML transcriptome, genome, and epigenome, leading to the identification of an increasing number of disease-associated alterations, indicating that the path to AML pathogenesis may be more complex. Data suggest that additional genomic and epigenomic events in leukemic cells may lead to further alteration of the leukemic clone and introduce genomic heterogeneity and clonal evolution within the leukemic cell population.

Disease-associated alterations in AML can be grouped into several broad categories. Large structural alterations, including duplications, deletions, and translocations, are identified by standard karyotype analysis in the majority of children with AML. Karyotypic abnormalities remain the most significant tools for diagnosis and also for defining prognosis in AML. More recently, disease-associated mutations of specific genes that mediate hematopoietic development have been identified that alter multiple signal transduction pathways and contribute to AML pathogenesis. Such mutations have come to define AML, as they are prevalent, provide prognostic information, and may act as potential targets for directed therapeutics. Additional areas are emerging as major contributors to the pathogenesis of AML, including regulation of translation by non-coding RNA (miRNA) and also epigenetic alterations due to aberrant DNA methylation and altered histone modifications.

Disease-associated genomic alterations, whether translocations, numerical structural alterations (monosomies, etc.), or sequence variations (mutations, indels), define AML biology and phenotype, and have been utilized as powerful tools for prediction of response and outcomes in subsets of patients.

Karyotypic alterations

The number of chromosomal alterations identified in AML is in excess of 300, although >70% of pediatric AML cases fall into several specific cytogenetic categories: 25% have CBF AML [t(8;21) or inv(16)], 12% have t(15;17), 20% have rearrangements involving the *MLL* gene, and 20% do not have karyotypic abnormalities (normal karyotype, NK). In addition to karyotypic alterations, disease-associated mutations can be identified in AML, with the highest prevalence in those with NK; >90% of pediatric AML cases have at least one genomic alteration (Figures 51.1 and 51.2).

Non-random numerical and structural chromosome aberrations have been identified in approximately 80% of children with AML and are considered to be major contributors in an early stage of disease development. Karyotypic alterations are regarded as one of the most significant biologic markers that define AML biology, and impact clinical outcome. Owing to the high correlation of recurrent karyotypic alterations with AML diagnosis and prognosis, the most recent World Health Organization (WHO) AML classification is primarily based on recurrent cytogenetic alterations. The most common genomic alterations in childhood AML involve CBF transcription factors, where translocations involving genes encoding CBFα (*RUNX1*) or CBFβ (*CBFB*) are detected in those with t(8;21) and inv(16), respectively, and occur in nearly 25% of children with AML. Core binding factor AML is considered a favorable prognostic factor, and those with t(8;21) or with inv(16) have a longer duration of remission and lower relapse risk, leading to significantly improved outcomes. The mixed leukemia lymphoma gene (*MLL*, 11q23) is a methyltransferase that is involved in the regulation of *Hox* gene expression and methylation of histone residues. Translocations involving the *MLL* gene are common in children with AML and account for nearly 20% of all cases of AML. In vitro data have demonstrated that MLL fusion proteins can transform hematopoietic precursors to leukemia-initiating cells, implicating this gene in stem-cell maintenance and hematopoietic regulation [8]. In *MLL* rearrangements, the N-terminus of *MLL* can be juxtaposed to the C-terminus of over 50 different partners, resulting in the loss of the methyltransferase domain. There is an association of the translocation partner with clinical outcome; those with t(6;11) and t(10;11) have a particularly poor outcome compared with other *MLL* translocations.

In addition to the common translocations outlined above, less common structural alterations are described with variable biology and prognostic significance. Notable examples are monosomy 7 (−7),

monosomy 5 (–5) and deletion 5q (del5q). These alterations cumulatively account for <5% of cases of childhood AML. Although specific genes in these chromosomal regions that contribute to disease pathogenesis have not been identified, the presence of these alterations is associated with high rates of induction failure and extremely poor survival [9]. Given the large age distribution within pediatric patients spanning birth to young adulthood, it is not surprising that there is significant age associated variation in cytogenetic abnormalities (Figure 51.1). There is a high prevalence of MLL in infants and young children, where nearly 50% of those younger than 2 years of age have an *MLL* translocation. In contrast, t(8;21) or inv(16) and those with NK are uncommon in infants and young children and their prevalence increases with age, approaching the prevalence observed in adult AML by age 5–10 years.

Somatic mutations

Somatic mutations in genes known to contribute to hematopoiesis have been identified in a significant proportion of children with AML and have been associated with clinical outcome. The most common somatic mutation in childhood AML is the *FLT3* internal tandem duplication (*FLT3*/*ITD*). It is detected in 15% of all children with AML with age-associated variation that increases from almost none in the first year of life increasing by age 10 years to the 20% prevalence reported in adult AML (Figure 51.2). The presence of *FLT3*/*ITD* has been associated with significant leukocytosis, increased induction failure, high rates of postremission relapse, and dismal survival [10]. In contrast, patients with mutations in *NPM* and *CEBPA* genes, have an excellent response to induction chemotherapy, a lower risk of relapse, and survival rates similar or superior to those with CBF AML. Additional somatic mutations, including *KIT*, *RAS*, *RUNX1*, and *WT1* have been identified in childhood AML. Although these groups are biologically distinct, they have not been demonstrated to have prognostic significance. Despite lack of prognostic significance, such somatic mutations may be used for directing targeted therapy. Recent application of whole genome sequencing to interrogate the AML genome in adult AML has identified a number of recurrent, clinically significant mutations [11]. Similar whole genome approaches have been performed in children have revealed novel disease-associated mutations [12] that once validated in multicenter clinical trials are likely to identify new class of biomarkers for risk stratification and therapeutic intervention.

The role of HCT in CR1 AML

Autologous versus allogeneic versus chemotherapy approaches

Early studies of HCT for CR1 AML patients sought to define whether autologous or matched family donor (MFD) allogeneic transplant approaches offered a survival advantage over chemotherapy. Table 51.1 summarizes the outcomes of autologous HCT compared with chemotherapy from studies performed in the 1980s and 1990s. All of the studies found no significant difference in OS or disease-free survival (DFS) in the two groups [1,13–17], except in the MRC-AML10 report. This study reported improved DFS with autologous HCT ($p = 0.02$), but no advantage for OS (OS 59% with chemotherapy and 70% with autologous HCT, $p = 0.2$) [17]. These studies show clear evidence that in children with newly diagnosed AML, autologous HCT offers no advantage over chemotherapy. Figure 51.3 shows the OS from the Children's Cancer Group (CCG)-2891 study comparing three different postremission regimens, where the survival difference in patients receiving chemotherapy or autologous HCT is identical and inferior to those receiving allogeneic HCT ($p = 0.006$) [1].

Table 51.2 summarizes the outcomes of studies comparing allogeneic HCT with chemotherapy for children with AML in CR1. Alonzo et al. reported the consolidation therapy results of five consecutive CCG studies (251, 213, 2861, 2891, and 2941), which included a large population of 1464 children [13]. Children in CR1 were allocated to receive an allogeneic HCT if a MFD was available. If an MFD was not available, the remaining children were assigned to consolidative chemotherapy or autologous HCT. Children assigned to receive an allogeneic HCT were found to have a significantly better OS, DFS, and relapse rate by intent-to-treat (ITT) analysis compared with those without an MFD, whether they received chemotherapy or an autologous HCT [13]. Similar results were seen in the majority of studies, where statistically significant differences were seen in outcomes for allogeneic HCT over chemotherapy alone [1,13,14,18–21]. These studies demonstrated that allogeneic HCT can offer an advantage over chemotherapy due to a GVL effect; however, as discussed below, careful definition of risk is important in defining when allogeneic HCT is most likely to result in a clinical benefit.

Risk-based therapy in CR1 AML: current role of allogeneic HCT

Although it is generally accepted that patients in second remission should receive HCT from the most suitable allogeneic donor, approaches to who should be considered for HCT in CR1 have evolved over the last two decades. The studies outlined in Table 51.2 made HCT using an MFD in first CR (CR1) the standard of care for treatment of childhood AML. Patients with –7 and –5/del5q were found to have an extremely poor outcome with conventional chemotherapy; therefore, more recent Children's Oncology Group (COG) trials allocated this small cohort of high-risk patients to HCT from any suitable donor, including unrelated donors. This occurred as advances in unrelated donor HCT in children were noted to result in better survival [22]. Further, patients with favorable risk cytogenetics (CBF AML) were shown to have similar survival regardless of whether they were treated with chemotherapy or HCT, questioning the utility of HCT in patients with more favorable outcome [23]. Hence those with CBF AML were not assigned to allogeneic HCT in CR1 even if a matched donor was

available. In this cytogenetic risk-based therapy allocation, 5% of the patients would be considered high risk, 20% would be in the favorable risk category, and the majority of patients would remain in the standard risk category and would receive HCT in CR1 if an MFD was available. More recently, incorporation of AML-associated mutations into clinical decision-making expanded the risk cohorts for therapy allocation. In this model, those with mutations in the *NPM* and *CEBPA* would be considered low risk and receive chemotherapy only [24,25], whereas those with *FLT3/ITD* would be allocated to the high-risk arm of therapeutic protocols [10]. Addition of these mutations modestly increased high- and low-risk cohorts, and the standard-risk cohort remained at nearly 65%.

Many investigators have shown that response to chemotherapy is a powerful predictor of outcome. In addition, sensitive methodologies, including multidimensional flow cytometry (MFC), have been used to define relapse risk in patients without known cytogenetic or molecular markers. COG AML protocol AAML03P1 collected comprehensive cytogenetic characteristics, mutation profiles (*FLT3/ITD*, *CEBPA*, and *NPM* mutation status), and MFC data, and demonstrated that in patients without known molecular prognostic markers [standard-risk (SR) cohort], MFC was able to identify the presence of MRD in nearly 30% of patients. In this SR cohort, those with MRD after AML induction therapy had a significantly worse survival than those who did not have evidence of MRD (26% vs. 67%, $p < 0.001$). This study also demonstrated that the presence of MRD in those with high- or low-risk disease was not associated with outcome [7]. As a result, a two-tier risk-based allocation system has been devised and implemented in the COG AML trials, where those with either high-risk cytogenetic and molecular features or those with otherwise SR disease with MRD are allocated to the high-risk arm of the study and receive HCT from the most suitable donor in CR1. The remaining patients, those with favorable cytogenetics/mutations or the MRD-negative SR cohort, are considered at favorable risk and would not receive HCT in CR1 regardless of the availability of matched family donors. Whether this revised risk-based approach to CR1 HCT is better than current approaches awaits the outcome of ongoing studies.

An alternative approach to CR1 transplantation is advocated by some study groups in Europe. A meta-analysis confirmed the findings outlined above about the efficacy of CR1 transplantation in patients with low-, intermediate-, and high-risk disease, but when only ITT studies were reviewed, as many as 10 patients were required to undergo transplantation to prevent one relapse, and salvage rates for relapse brought survival curves of donor versus non-donor patients closer together [5]. With this in mind, some European groups advocate limited up-front HCT, focusing on allogeneic HCT interventions to salvage patients who relapse. This approach has not been compared directly with up-front approaches to HCT; how such an approach compares with refined risk-based approaches being used in North America awaits further study.

The role of allogeneic HCT in CR2 + AML

Despite improvements in overall outcomes in children with AML, approximately 40% will die from relapsed disease or from toxicities related to intensive treatment. Allogeneic HCT is the best chance for cure in patients with AML who relapse, regardless of their initial risk classification (Table 51.3). Webb et al. described patients who relapsed after initial treatment in the United Kingdom Medical Research Council (MRC) AML 10 trial [26]. Not all children were treated, but of those given chemotherapy, 69% attained a CR2. The 3-year OS rate was 24%; however, the DFS was 44% for those who achieved a CR2. The most important factor affecting survival was the length of CR1. Aladjidi et al. reported on the French experience from the LAME 89/91 trial, where 71% of patients who relapsed after a CR1 were able to achieve CR2 following one to three cycles of chemotherapy [27]. HCT was performed in 78% of patients and the 5 year OS was 33%; DFS was 45% if patients achieved CR2. Similarly to the MRC AML 10 trial, this study highlighted the fact that the main prognostic factor for overall survival was the length of time to relapse from CR1.

Nemecek et al. reported the Seattle experience of patients in CR2 receiving a first HCT from a related or unrelated donor, where the estimated 5-year DFS was 58% [28]. Relapse estimates after HCT were still high at 42%, but these data were promising since DFS was higher than seen in previous studies. Bunin et al. described prognostic factors that influenced outcome after unrelated donor HCT in children with AML using NMDP data [29]. For patients in CR2, 5-year OS was 47% and the only risk factor that predicted all major outcomes was disease status at the time of transplant.

Investigators from the Berlin–Frankfurt–Münster (BFM) group analyzed the outcome of 379 children who relapsed as late as October 2007 out of 1251 children enrolled on the AML-BFM 87,

93, and 98 trials [30]. The 5-year OS for patients treated with curative intent was 29% (86% chose intensive therapy), with an increase in survival from 18 to 34% over the period of the trial. Late relapse (>12 months from diagnosis), age <10 years, no HCT in CR1, and favorable cytogenetics were independent predictors of survival. The most important determinant of outcome, however, was whether patients achieved a complete remission with induction chemotherapy. A total of 63% achieved a second remission and OS was 44% of those achieving CR2 compared with 3% of those who did not ($p < 0.0001$). Outcomes with chemotherapy were similar to those receiving HCT (35 vs. 46%, $p = 0.11$), but those treated with chemotherapy had a greater likelihood of having experienced a late relapse or a relapse isolated to the extramedullary space. Because these groups have very different risks, directly comparing the chemotherapy with the allogeneic HCT outcomes in this group is not meaningful.

Finally, investigators from the Therapeutic Advances in Childhood Leukemia (TACL) Consortium reviewed 99 patients with relapsed or refractory non-APL AML treated at nine institutions between 1995 and 2004 [31]. It was reported that 56 ± 5% of patients achieved remission with the first reinduction attempt, with 25 ± 8% succeeding after a follow-up induction attempt and 17 ± 7% after any subsequent attempts, illustrating that if early remission is not achieved, multiple attempts are less likely to result in remission. Early relapses (<12 months from diagnosis) were less likely to achieve remission with first reinduction (83% vs. 51%). In multivariate analysis, 5-year DFS was improved in patients whose CR1 duration was ≥12 months (65 ± 11%) compared with a CR1 duration of <12 months (38 ± 11%) versus not achieving CR1 (0%, $p = 0.002$). Receiving HCT as consolidation therapy was associated with a marked improvement in survival in multivariate analysis [hazard ratio (HR) 0.29, $p < 0.001$], whereas factors such as age, cytogenetic risk group, and white blood cell (WBC) count at diagnosis were not associated with event-free survival (EFS) or OS [31]. These studies define a clear role for allogeneic transplantation in the treatment of relapsed, non-APL AML, and show that early relapse and delayed or inadequate remission prior to HCT are key risk factors for poor prognosis.

A limited role for autologous HCT in CR2 AML

In CR1, there is a clear advantage to allogeneic HCT over autologous HCT; however, in CR2, some reports hint that in highly selected lower risk patients, autologous approaches yield survival rates that approach those of allogeneic HCT (Table 51.4). In a review of CIBMTR (Center for International Blood and Marrow Transplant Research) data, Godder et al. showed that that the probability of leukemia-free survival (LFS) at 3 years was 60% versus 23% in children undergoing autologous HCT in CR2 who relapsed <12 months from diagnosis compared with those who relapsed later, mainly due to high relapse (60%) in the <12 months from diagnosis group [32]. Other reports show reasonable survival using autologous approaches for patients with low-risk cytogenetics or APL who relapse late, especially if those patients achieve an MRD-negative CR and the autologous product harvested for the procedure is polymerase chain reaction (PCR) negative for a molecular marker [33,34]. Although many clinicians favor sibling HCT for AML patients in CR2 not transplanted in CR1, consideration of autologous approaches is reasonable for patients with relapses ≥12 months from diagnosis, especially if a deep remission can be achieved and if the patient has favorable prognostic factors or poor donor choices.

Outcomes of children undergoing HCT with AML not in remission

Chemotherapy-refractory AML, either at diagnosis or after relapse, has been treated with HCT by some investigators hoping either (1) to overcome chemotherapy resistance with high-dose chemo/radiotherapy or (2) to use the GVL effect immunologically to cure patients. Survival rates have been poor (range 2–32%) and concern about selection and reporting bias has made understanding the relevance of the published literature difficult [28,35,36]. An early IBMTR study offered insight into some characteristics that may help define subgroups of patients who could benefit from HCT [37]. The study reviewed 88 patients with non-remission AML undergoing HCT from 1982 to 1989 at multiple centers. The three-year

LFS was 21%. Independent associations with improved survival included (1) fewer than 25% blasts on bone marrow (BM) biopsy, and (2) fewer rounds of induction chemotherapy (2 or 3 versus >4). In addition, relapse was decreased in patients without circulating blasts. Duval et al. performed a more contemporary analysis (myeloablative HCT between 1995 and 2004) of 1673 patients reported to the CIBMTR with AML refractory to induction or reinduction therapy at the time of HCT [38]. The 3-year OS of the cohort was 19%, and the five pre-transplantation variables that independently correlated with worse survival on multivariate analysis were (1) CR1 <6 months, (2) presence of circulating blasts at HCT, (3) use of donors other than matched siblings [matched unrelated donor better than mismatched related donors (including haploidentical donors)], (4) Karnofsky/Lansky score <90, and (5) poor-risk cytogenetics. Recipients with none of these risk factors had a 3-year OS of 42% (95% CI 34–50%), whereas those with one, two, or three of these factors had survivals of 28% (95% CI 23–33%), 15% (95% CI 11–19%), and 6% (95% CI 3–9%), respectively. This and other studies point to survival in the 20–40% range of a selected cohort of children with active AML at HCT. The optimal transplant approach has not been defined, as published responses have been observed using myeloablative and reduced-intensity regimens.

Pre-HCT MRD positivity: effect on survival

The complexity of gene rearrangements has made PCR-based detection of MRD for AML challenging; however, over time, PCR-based methods, MFC, and assays of *WT1* gene expression have been developed and are now being routinely used pre- and post-HCT for prognostic indications and screening [39]. Flow cytometric approaches developed by the COG and St. Jude's AML groups have shown that the persistence of MRD in newly diagnosed patients after the first induction regimen defines a group at very high risk for relapse [7,40], validating the use of flow cytometry in a multicenter pediatric setting. In a mixed adult and pediatric cohort, investigators in Seattle reported a marked decrease in survival for patients with >0.01% MRD detected by flow cytometry pre-HCT compared with those who were negative or had lower levels [2-year OS 30% (95% CI 13–49%) vs. 77% (95% CI 64–85%), MRD positive vs. negative], with the difference being explained by a marked increase in relapse in MRD-positive patients [2-year relapse estimate 65% (95% CI 42–86%) vs. 18% (95% CI 10–28%)] [41]. Multivariate analysis adjusting for cytogenetic risk and other key AML risk factors confirmed that the presence of detectable pre-HCT MRD was associated with a markedly increased risk of overall mortality (HR 4.05, $p < 0.001$) and relapse (HR 8.49, $p < 0.001$).

Large pediatric-specific studies to establish better the role of pre- and post-HCT MRD in defining risks of poor outcome are under way in the COG and the Pediatric Blood and Marrow Transplant Consortium (PBMTC). Of note, two small pediatric studies offer some insight into this issue. Jacobsohn et al. [42] compared the outcomes of children with high MRD as measured by *WT1* expression pre-HCT with those with low *WT1* expression. Patients with high *WT1* expression had a lower 5-year EFS than those with low expression (18% vs. 68%, $p = 0.007$). Leung et al. [43] reported a single-center study of the predictive effect of the presence of pre-HCT MRD by flow cytometry in 122 children [AML, $n = 58$; acute lymphoblastic leukemia (ALL), $n = 64$]. They noted a strong effect of pre-HCT level on survival, with MRD-negative, low-positive, and high-positive patients surviving at rates of 68, 52, and 29%, respectively ($p = 0.0019$) (Figure 51.4).

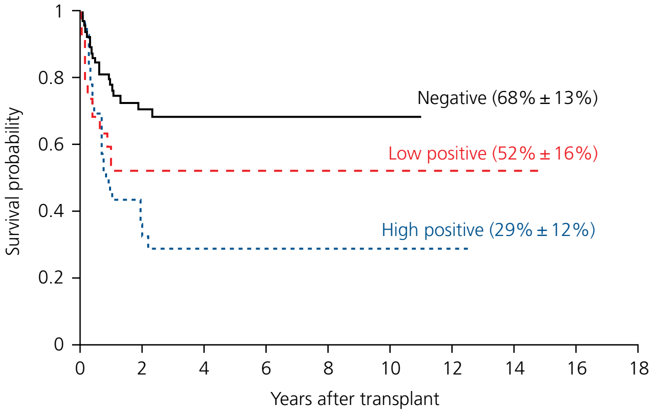

Figure 51.4 Effect of pre-HCT MRD level on survival in children with AML and ALL [2].

Although pre- and post-HCT measurement of MRD clearly predict poor outcomes, survival estimates of MRD-positive patients with AML after HCT range from 30 to 60%; therefore, transplantation is still indicated for MRD-positive patients if multiple attempts to achieve MRD-negative remissions have failed. It is not clear whether sequential rounds of chemotherapy or other strategies to reduce MRD pre-HCT will improve survival, but studies looking at this question are under way.

The role of HCT in acute promyelocytic leukemia

Acute promyelocytic leukemia (APL) has distinct biology [characteristic translocation of the *PML-RARA* genes, t(15;17)], and presentation compared with other AML subtypes. The addition of all-*trans*-retinoic acid (ATRA) to anthracycline-based regimens has dramatically improved outcomes, making early remission HCT unnecessary [44]. More recent development of arsenic trioxide monotherapy, initially for salvage therapy [45] and later for combined therapy with ATRA [46], has further limited the need for HCT, as only rare patients are refractory or relapse.

In cases where patients are (1) unable to receive these key medications (reached anthracycline limits, intolerant of ATRA or arsenic trioxide), (2) resistant or refractory, or (3) otherwise at high risk for poor outcome with chemotherapy approaches (mainly patients suffering one or more relapses), both autologous and allogeneic approaches have resulted in successful long-term survival. Retrospective pediatric studies have demonstrated long-term survival of APL patients undergoing allogeneic or autologous HCT in remission exceeding 70% [33,47]. The choice of allogeneic versus autologous stem-cell source should be made based on the quality of remission and degree of match of the related or unrelated donor. Patients who achieve a PCR-negative remission and then have a hematopoietic cell product harvested that is also PCR negative have achieved long-term survival approaching 80%, compared with 50% survival when PCR negativity has not been achieved [48]. A separate report documented relapse in all seven patients receiving autologous HCT with PCR-positive products, but in only one of eight patients who received PCR-negative products [49]. A further study demonstrated a superior 5-year survival in patients with relapsed APL who underwent autologous HCT in second molecular remission compared with maintenance therapy with arsenic trioxide or arsenic trioxide–ATRA combination regimens (83.3% vs. 34.5%, $p = 0.001$)

[50]. Although no studies randomly comparing autologous versus allogeneic approaches or consolidation with transplant versus chemotherapy have been performed in CR2, the data above support a role for autologous transplantation when products are PCR negative and patients can tolerate a myeloablative regimen in relapsed and other patients at high risk for failure with chemotherapy approaches.

The role of HCT in therapy-related AML

Studies addressing HCT for adult patients with therapy-related AML (t-AML) showed poor rates of survival due to high non-relapse mortality (NRM) and high relapse rates [51]. Some improvement in survival has been noted with targeted busulfan/cyclophosphamide and other non-total body irradiation (TBI)-based regimens [52], but poor prognosis after transplant has been associated high levels of adverse cytogenetics [53]. There are only a few reports describing the outcome of children undergoing HCT for therapy-related AML. Woodard et al. [54] described 27 children with t-AML receiving related and unrelated donor HCT. Three-year OS and EFS were 18.5 ± 7.5% and 18.7 ± 7.5%, respectively. Poor survival was mainly due to very high treatment-related mortality (TRM) (59.6 ± 8.4%). Aguilera et al. [55] reported a second retrospective single-center experience of 14 patients transplanted for t-AML/therapy-related myelodysplastic syndrome (t-MDS) between 1975 and 2007. Survival was 29%, but in this review only 63% of patients diagnosed with tMDS/tAML underwent HCT. A multicenter study from the CCG (2891) looked at outcomes of 24 children with t-AML/t-MDS compared with other children enrolled on the study with de novo AML ($n = 898$) or MDS ($n = 62$) [56]. Children with t-AML/t-MDS were older and low-risk cytogenetics rarely occurred. Although rates of achieving CR and OS at 3 years were worse in the t-AML/t-MDS group (CR rate 50% vs. 72%, $p = 0.016$; OS 26% vs. 47%, $p = 0.007$), if patients achieved a CR, survival was similar (OS 45% vs. 53%, $p = 0.87$). The importance of remission to survival in these patients is further illustrated by another single-center experience. Kobos et al. [57] described their studies of 21 children undergoing HCT for t-AML/t-MDS performed between 1994 and 2009. Eleven of 12 children with t-AML were in remission at the time of HCT, seven had refractory anemia (RA), and two had refractory anemia with excess blasts (RAEB). Survival of the entire cohort was 61%; those in remission or with RA had a DFS of 66%, and those with >5% blasts at the time of HCT had 0% survival ($p = 0.015$).

Because t-AML is rare in children, it is not known whether the significant decrease in TRM after unrelated donor HCT noted over the past several years will translate to improved survival in this population. Patients should be carefully assessed for pre-HCT morbidities caused by earlier therapies and approaches should be adapted to give adequate intensity while minimizing TRM.

Effect of hematopoietic cell source on outcomes

Related versus unrelated donors for children with AML

The use of HLA-matched related donors as the first choice for hematopoietic cell source has long been recognized. Since at most 20–30% of patients who need an HCT will have a matched related donor, the use of unrelated donors (URDs) has increased, and most data suggest similar outcomes to related donors. One of the early pediatric-specific URD experiences was published by investigators at the Medical College of Wisconsin, who reported outcomes of 50 children who received a URD HCT at their center between 1986 and 1991. The EFS for all patients was 44% and OS was 50% with a median follow-up was 49 months. These data were similar to published reports for children transplanted with HLA-matched sibling donors at the time and led to URDs being considered a favorable option for children requiring HCT [58]. The Seattle group reported their experience with 87 children who were transplanted with a URD and showed similar outcomes to the Wisconsin group [59]. They later reported their experience of URD HCT for AML, which included 26 pediatric patients (16% of the cohort). LFS was 50% for transplants in CR1, but only 28% for those transplanted in CR2. Favorable prognostic factors included receiving HCT during remission, a marrow cell dose above 3.5 × 10^8/kg and cytomegalovirus (CMV) seronegative status in both the donor and recipient before HCT [60].

Since 2000, significant improvements in survival after URD HCT have occurred in children with AML. Children transplanted between 2003 and 2006 had 2-year EFS of 69, 66, and 36% compared with 42, 30, and 28% a decade earlier for HCT in CR1, CR2, or >CR2/relapse, respectively. The most important improvement over time was a marked decrease in TRM (1-year TRM 40% in 1987–1995 vs. 15% in 2003–2006, $p < 0.001$) (Figure 51.5) [6]. It is not clear which elements of the HCT process have led to improved survival, but better HLA typing/matching, improved supportive care, and possibly better patient selection, with reduced-intensity approaches given to patients with comorbidities, may have contributed.

With these more modern data in mind, most agree that current survival outcomes after URD HCT are comparable to those for matched sibling HCT. A Korean study showed identical survival with matched URD recipients undergoing HCT in CR1 versus sibling donor recipients [61], and a large CIBMTR study showed only a slight advantage in survival of matched sibling donor recipients compared with fully matched URD or mismatched/or matched non-sibling related donors recipients [62]. It is important to note, however, that the CIBMTR analysis clearly illustrated that although survival after matched URD HCT or mismatched related donor HCT is similar to that in sibling donor procedures, the non-survival outcomes are very different. URD and mismatched or non-sibling

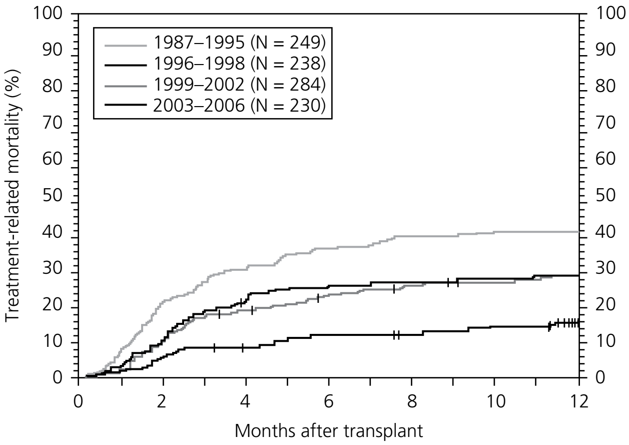

Figure 51.5 Decreasing transplant-related mortality after unrelated donor bone marrow transplantation. Source: MacMillan et al. 2008 [6]. Reproduced with permission of Elsevier.

donor procedures result in higher rates of significant acute and chronic graft-versus-host disease (GVHD) and increased TRM. With these risks in mind, some cooperative groups distinguish between indications for sibling donor HCT versus URD HCT, reserving URD HCT for higher risk clinical scenarios.

T-cell depletion of matched related or unrelated donors in AML

T-cell depletion techniques have varied through the years, but have almost always been associated with higher rates of graft rejection and relapse. Because of this, the approach has generally been practiced at a small number of centers with a special research emphasis in this area. In the past several years, however, with the advent of high-quality magnetic bead separation techniques, multicenter phase II trials have been successfully performed in younger adult patients with CR1 and CR2 AML undergoing myeloablative procedures [63]. Results from a recent phase II Blood and Marrow Transplant Clinical Trials Network (BMT CTN) trial of young adult patients undergoing T-cell-depleted matched sibling HCT for AML in CR1 and CR2 were compared with a matched cohort of CR1 and CR2 patients with AML enrolled on other contemporaneous BMT CTN trials who received standard approaches to GVHD prophylaxis (calcineurin inhibitor plus methotrexate) [64]. Engraftment rates were similar between the T-cell-depleted patients and matched controls, day 100 rates of acute GVHD were marginally improved (23% vs. 39%, $p = 0.07$), and 2 year cumulative incidence of chronic GVHD was markedly improved (19% vs. 50%, $p < 0.001$). Rates of graft rejection, relapse, TRM, DFS, and OS were the same in two groups. Of note, all of the T-cell-depleted cohort underwent a TBI-based regimen, whereas half of the matched cohort used chemotherapy-based regimens. There are limited publications demonstrating the successful use of this approach in pediatric patients [57,65], including related approaches such as in vivo depletion using alemtuzumab [66]. No prospective trials comparing T-cell depletion with standard approaches that include pediatric patients have been performed. Therefore, although the data for adults are intriguing, further study is required in pediatrics before this approach could be generally adopted. The data for T-cell depletion of haploidentical donors, especially those with favorable killer immunoglobulin receptor (KIR) donor–recipient combinations, are more abundant and are reviewed in Chapter 11, which is focused on natural killer cell- and KIR-related approaches.

Cord blood outcomes in children with AML

Although acceptable unrelated donors (currently 7/8 or 8/8 HLA allele matched) can be found in the majority of Caucasian patients, Black, Asian-Pacific islanders, and Hispanic recipients are much less likely to have acceptable matches in the registry [67]. Because cord blood matching requirements are less stringent (currently 4/6 HLA antigen/allele matched with adequate cell dose), studies have shown that >95% of recipients can find acceptable units [68]. Early studies established the safety and efficacy of unrelated umbilical cord blood transplants [69]. Investigators from Minnesota performed a comparison of pediatric patients transplanted with either HLA-mismatched URD cord blood grafts or HLA-matched BM and showed that neutrophil recovery was slower after cord blood transplant, but platelet recovery, rates of acute and chronic GVHD, and OS were similar in the groups [70]. To evaluate multiple donor strategies, Rocha et al. compared the outcomes of children receiving cord blood unit transplant with those receiving either a URD BM transplant or a T-cell-depleted URD BM transplant in a retrospective multicenter study [71]. Patients who received a cord blood transplant were more likely to have HLA mismatches, delayed hematopoietic recovery, decreased acute GVHD, and increased TRM at 100 days. EFS was similar in all three groups, suggesting that cord blood transplantation is a reasonable option for children with acute leukemia without a suitable matched unrelated BM donor. The Eurocord Group later published results of URD cord blood transplantation specifically in children with AML [72]. They found acute GVHD in 35%, 100-day TRM in 20%, a 2-year cumulative incidence of relapse of 29%, and a 2-year LFS of 42%. LFS was highest for children in CR1 (59%) than in CR2 or not in a CR (50 and 21%, respectively). These and other studies show that matched or mismatched URD cord blood units can be used as an alternative donor source for children with AML who are undergoing an HCT and survival is comparable to that with other hematopoietic cell sources.

Haploidentical approaches to children with AML

A final alternative hematopoietic cell source for children with AML is the use of partially matched or haploidentical family donors. These donors are readily available because parents or siblings can be used and offer an advantage for patients who need to go to transplant quickly. Godder et al. described the use of partially mismatched related donors as hematopoietic stem cell sources in pediatric patients with acute leukemia [73]. They used partial T-cell depletion along with immune suppression. They found that 96% of patients engrafted, 24% developed acute GVHD, and the 3-year relapse rate was 41%. This study showed that the use of partially mismatched related-donor HCT is feasible in pediatric patients with acute leukemia. Marks et al. reported on 34 children who underwent a haploidentical HCT for acute leukemia [74]. They received cyclophosphamide and TBI for conditioning, followed by infusion of T-cell-depleted peripheral blood hematopoietic cell grafts. The OS at 2 years was 26% and the major determinant of outcome was the disease state at the time of HCT. No child transplanted with refractory AML survived, suggesting that this approach is unlikely to be beneficial for children if their disease is not in remission. The major barriers to OS were infection and relapse. More contemporary experiences with haploidentical transplantation for children with AML are likely impacted by the selection of KIR favorable donor–recipient combinations (see Chapter 11 for a discussion of natral killer cell and KIR approaches), but have also benefited from significant decreases in TRM, especially as a result of decreased infection-related mortality due to better viral screening and antimicrobials. Researchers at St. Jude demonstrated significant improvements in recent outcomes compared with those a decade earlier [5-year OS for AML patients 77% (95% CI 35–94%) versus 22% (95% CI 3.4–51%)] using haploidentical approaches [75]. These results make haploidentical approaches a viable alternative when performed by centers experienced in the procedure.

Preparative regimens for pediatric AML patients

Most published pediatric approaches to AML have utilized myeloablative regimens, mainly busulfan/cyclophosphamide (BU/CY)- or TBI-based approaches. A small retrospective study published in 1994 of 74 children in CR1 undergoing HCT using matched family donors compared BU/CY with cyclophosphamide dosed at either 120 or 200 mg/kg with TBI-based conditioning [76]. A significant decrease in relapse was noted in the BU/CY 200 mg/kg–cyclophosphamide dose cohort compared with the 120 mg/kg dose group ($p = 0.02$);

however, the resultant improvement in survival did not reach statistical significance ($p = 0.07$). Children undergoing TBI-based approaches had survival identical with that for patients receiving BU/CY 200 mg/kg. Because of equivalent outcomes compared with TBI-based regimens and less relapse compared with BU/CY 120 mg/kg, the BU/CY 200 mg/kg regimen was adopted by the COG and other groups as a standard preparative approach for patients with CR1 AML undergoing MFD HCT.

Although BU-based regimens have been widely used for matched related donor AML in CR1, most pediatric groups have used TBI-based approaches for URD HCT for AML through the 1990s and first decade of the 2000s [29]. Recent data have questioned the need for TBI for patients undergoing URD HCT. A retrospective study of the PBMTC compared TBI-based with BU-based regimens in 151 children undergoing unrelated (99) or related (52) donor HCT for AML beyond CR1 [77]. At 6 years after HCT, no difference was noted in relapse [31% (95% CI 17–45%) BU/CY vs. 24% (95% CI 15–34%) TBI; $p = 0.74$], TRM [20% (95% CI 7–30%] vs. 32% (95% CI 17–43%); $p = 0.289$], EFS [37% (95% CI 19–70%) vs. 45% (95% CI 35–58%); $p = 0.293$], and OS [56% (95% CI 43–72%) vs. 45% (95% CI 35–58%); $p = 0.117$]. The CIBMTR retrospectively compared outcomes in 1593 patients (192 aged <20 years) undergoing HCT for AML, chronic myelogenous leukemia (CML), and MDS who received BU/CY, compared with TBI at standard doses (>1000 and <1260 cGy) or high doses (>1320 and <1500 cGy) [78]. Although high-dose TBI led to more grade III–IV acute GVHD ($p = 0.011$), relapse, TRM, DFS, and OS were comparable between the three groups. With these data in mind, BU/CY has become an acceptable approach for children at any stage of response with either related or unrelated donors.

Studies in adults attempting to decrease hepatic toxicities associated with BU/CY have substituted fludarabine for cyclophosphamide with dramatic decreases in TRM. Andersson et al. compared busulfan/fludarabine (BU/FLU) with a retrospective cohort of patients treated with BU/CY 120 mg/kg and, after adjusting for treatment period differences, the BU/FLU group had a 20% increase in 3-year survival, mainly due to decreased TRM [79]. Prospective randomized comparisons of this approach with BU/CY have not been performed. Another promising preparative regimen using treosulfan (Treo), a conjugate of BU with less liver toxicity, has been described. Nemecek et al. described remarkably low levels of TRM (8% at 2 years) with 2-year relapse free survival (RFS) of 88% in patients without high-risk cytogenetics [80]. The COG is currently exploring the role of BU/FLU in children with high-risk CR1 AML and the PBMTC is studying a combination of treosulfan, fludarabine, and mini-dose TBI in pediatric patients with AML or MDS. These trials and possible future direct comparative trials will determine whether "reduced-toxicity" myeloablative approaches such as BU/FLU or Treo/FLU result in similar or improved survival compared with BU/CY.

Reduced-intensity conditioning (RIC) regimens in pediatric AML

The regimens described above are considered intense, myeloablative approaches. In the past decade, however, a variety of approaches have been developed that utilize the GVL effect and focus on preparative agents that substitute potent immunosuppression for more toxic myelosuppression. The intensity of these approaches varies, and has been grouped into three major categories: non-myeloablative (NMA) (just enough to establish donor engraftment), reduced-intensity (RIC) (establishes engraftment and gives some intensity for disease control), and myeloablative (MA) (significant intensity). A large CIBMTR study comparing the three approaches in AML showed equivalent 5-year survival between MA and RIC, but a slight disadvantage for NMA regimens [81]. The patients receiving NMA approaches were older, however, and may have had unmeasured comorbidities that contributed to the slightly inferior outcome.

A number of individual pediatric centers have used RIC approaches for children with AML [82–84]. Outcomes in centers using RIC regimens as preferred approaches seem to be similar to those with traditional MA approaches, but selection bias is a concern. Because pediatric patients can generally tolerate intensive MA regimens, many of the early studies of RIC included only patients ineligible for standard MA HCT because of organ toxicity, history of infection, or other reasons. With this in mind, the published survival outcomes in the 40–60% range are encouraging. A multicenter PBMTC study of patients ineligible for MA regimens due to infection, organ toxicity, or previous MA HCT used a preparative approach of low-dose BU, FLU, and antithymocyte globulin (ATG). OS at 2 years was 45%, and was the similar between AML and ALL and between different stem-cell sources. Patients who were MRD negative pre-HCT had improved survival (2-year OS 63%) [85]. These studies show that RIC approaches can be used for pediatric patients in remission (especially MRD-negative remission) if they are ineligible for MA approaches. Studies randomizing MA with RIC or NMA regimens in pediatric patients with AML have not been performed and, until they are, MA approaches are still considered standard for children who are medically eligible.

The graft-versus-leukemia (GVL) effect in pediatric AML

Multiple studies have suggested that the GVL effect may contribute to the overall cure rate in patients with leukemia, although there is a delicate balance between GVL and GVHD. One of the first studies of this effect in children was reported by a Swedish group, where GVL and its relation to chronic GVHD were associated with improved survival and a reduced risk of relapse [86]. In patients with AML, the probability of relapse was reduced from 40 to 29% if patients developed chronic GVHD. Chronic GVHD also had a favorable effect on survival in the AML group, although this effect was greater in children with ALL. Acute GVHD was not found to be associated with a lower risk of relapse in this study. Another early report establishing the effect of GVL on survival in children with AML was the CCG 2891 study [87]. In this study, patients who developed grade III–IV acute GVHD had an inferior DFS of 15% at 6 years, compared with patients without acute GVHD or with grade I–II acute GVHD ($p < 0.001$). In the patients with grade I or II acute GVHD, the RFS was higher at 76 and 87%, respectively, compared with patients without acute GVHD, whose RFS was 62%. Although patients with grade III–IV acute GVHD had an inferior DFS, those patients who survived did not relapse from their disease. Chronic GVHD was also associated with improved RFS ($p = 0.05$) but the decreased rate of relapse did not correlate with an improved OS or DFS.

In an analysis by the CIBMTR describing the incidence and risk factors for GVHD in children receiving URD HCTs, the risk of relapse was significantly decreased in children with ALL who developed grade III–IV acute GVHD ($p = 0.0052$) but not in children with AML ($p = 0.26$) [88]. The reason why children with AML who developed acute GVHD and did not have a reduced risk of relapse was unclear. The authors postulated that competing mortality from severe GVHD might have overcome any benefit from GVHD, although the small sample size made it difficult to see statistically significant differences.

Some investigators have posited that early immune recovery after transplant leads to a GVL effect in the form of immune surveillance that decreases relapse with or without GVHD. Powles et al. described a multivariable analysis of 201 adult patients transplanted with HLA-matched sibling donors for AML [89]. Patients with absolute lymphocyte counts ≥0.2 × 10^9/L at day 29 after HCT had 3-year relapse probabilities of 16% versus 42% in patients with lower ALC at that point ($p = 0.004$), translating into improved survival (66% vs. 35%, $p = 0.003$). This observation remained significant on multivariate analysis (relative risk for relapse 2.9, $p = 0.02$), and was independent of GVHD. Although a pediatric group showed that this observation was valid in children with ALL after HCT [90], a follow-up study of children with AML after HCT was not able to demonstrate an association with early lymphocyte recovery and GVL [91]. It is not clear why children would be different from adults with AML, and further study regarding the importance of immune reconstitution to relapse in pediatric AML is required.

Relapse after HCT

The major determinant of outcome with relapse after transplant is whether families and physicians decide to treat patients with curative intent. Approaches vary, but generally only immunologic approaches [withdrawal of immune suppression, donor lymphocyte infusion (DLI), or second transplant after CR is achieved] result in long-term cure. Lee et al. reviewed the clinical course of 49 children at a single institution who relapsed with AML after HCT between 1993 and 2011 [92]. Of the 49 patients, 36 (73%) underwent intensive chemotherapy and 26 achieved CR (53%). The probability of OS at 5 years was 31.6 ± 8.7% for those who underwent intensive chemotherapy and 23% of the entire population. Bajwa et al. reviewed the outcomes of 160 consecutive relapses out of 532 patients transplanted between 1992 and 2010 at five pediatric centers [93]. ALL, AML, CML, juvenile myelomonocytic leukemia, secondary AML, acute biphenotypic leukemia, acute undifferentiated leukemia, and MDS were included. Relapsed patients received either palliative therapy (no curative intent, $n = 43$, 27%), salvage chemotherapy without second HCT ($n = 55$, 34%), or chemotherapy followed by a second HCT ($n = 62$, 39%). DFS at 2 years was 35% versus 2% in those who underwent a second HCT versus those who did not ($p < 0.0001$) (Figure 51.6). Multivariate analysis showed that improved survival was associated with (1) a longer time to relapse and (2) undergoing a second HCT. Withdrawal of immune suppression followed by chemotherapy and second HCT in those who achieve remission was recommended.

Immunologic interventions to treat AML relapsed after HCT

An approach taken by many transplant physicians if patients relapse while on immune suppression and GVHD is absent or controlled is withdrawal of immune suppression. Anecdotal reports of development of GVHD with resultant, sometimes long term, response have been published, but this approach rarely controls overt relapse effectively. Attempts to modulate immune suppression based upon detection of increasing recipient chimerism, a strong risk factor for relapse, have been pursued in pediatric AML. Bader et al. described the achievement of complete chimerism and continuous complete remission in two of three AML patients after withdrawal of cyclosporine [94]. Six other patients with ALL or MDS showed complete chimerism and continuous complete remission after withdrawal of cyclosporine and the addition of DLI. This study showed that treatment strategies guided by mixed chimerism can prevent relapse in children with AML after transplant, but this and other studies published were relatively small.

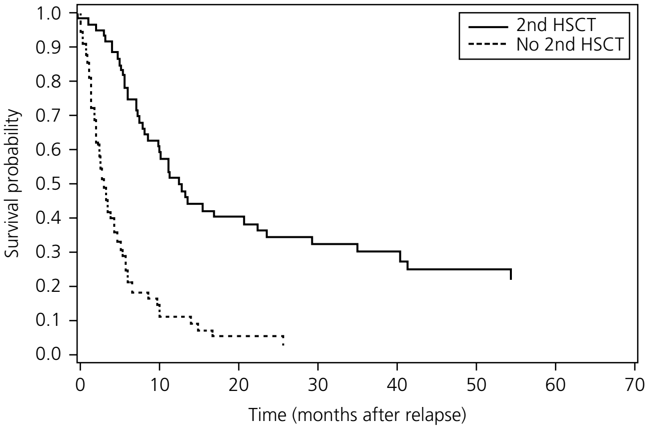

Figure 51.6 Outcome of treatment with curative intent followed by second HCT in children relapsing after first HCT. Source: Bajwa et al. 2012 [93]. Reproduced with permission of Nature Publishing Group.

There is greater experience using DLI to treat relapse after transplant for AML. An early report by the European Group for Blood and Marrow Transplantation (EBMT) evaluated the risks and benefits of DLI in recurrent leukemia in adults, including AML. Transfusion of donor lymphocytes induced complete remissions in five of the 17 patients with AML, but these remissions were not always durable [95]. Levine et al. reported a prospective trial in which patients with myeloid leukemia relapse were treated first with cytoreductive chemotherapy, followed by granulocyte colony-stimulating factor (G-CSF)-primed DLI [96]. The majority of patients had AML, ages ranged from 2 to 59 years, and the 2-year OS was 19%. It was concluded that salvage treatment with this approach may benefit some patients with myeloid relapse after HCT, especially those who relapsed >6 months after HCT. A CIBMTR study of DLI in pediatric patients showed very poor survival in children who relapsed <6 months after transplant (0/14) [97]. Of 16 patients with AML receiving DLI, 11 were not in remission. One was a long-term survivor and the other 10 relapsed. The remaining five received chemotherapy and achieved a CR prior to DLI, and 3/5 remained alive at 3, 13, and 55 months. DLI for early relapse and patients with uncontrolled relapse leads to poor outcomes. Extramedullary relapse following chemotherapy and DLI approaches has been reported. Choi et al. treated patients with chemotherapy followed by DLI and reported a 2-year OS of 31% [98]. All five patients who relapsed after achieving a CR did so at extramedullary sites without BM relapse. This study and other data suggest that the central nervous system (CNS) is immunologically protected from DLI, and clinicians using DLI may need to use other approaches to CNS control.

Second HCT

If remission can be achieved with chemotherapy after a post-HCT relapse, a second HCT can lead to long-term survival in a portion of patients. Michallet et al. reported the French experience of a second

HCT after relapse of acute and chronic leukemia in pediatric and adult patients [99]. Pediatric patients achieved a 2-year OS of 50% with a DFS of 47% and TRM of 20%. Factors associated with a better outcome included age <16 years, relapse >12 months after the first HCT, and the occurrence of chronic GVHD. Meshinchi et al. described 25 pediatric patients who previously underwent an autologous (n = 11) or allogeneic (n = 14) HCT and subsequently relapsed [100]. These patients then underwent a TBI-based preparative regimen followed by a second transplant using related or unrelated donors. All patients engrafted and DFS at 10 years was 44%.

Although the majority of reports of successful second HCT in children describe myeloablative approaches, both the adult and pediatric literature suggests that RIC approaches can also be performed successfully. Pulsipher et al. reported a PBMTC study using a RIC regimen of low-dose busulfan/cyclophosphamide/ATG for children ineligible for myeloablative procedures, mostly due to relapse after previous HCT [85]. Children with a history of a previous transplant with a non-TBI regimen achieved a 2-year survival of 63% compared with 23% when the previous HCT involved TBI ($p = 0.02$). Very low survival was achieved when disease was present by flow cytometry, emphasizing that deep remission is required for success with RIC approaches. These approaches show reasonable outcomes with second HCT after relapse using either myeloablative or RIC approaches if remission is achieved and the interval after first HCT is at least 6–12 months [100].

Conclusions – targeted chemotherapeutic, HCT, and cellular approaches to pediatric AML

Tremendous progress over the past two decades has fundamentally changed approaches to HCT for AML in children. After early data showed an advantage of sibling donor allogeneic approaches over autologous HCT or chemotherapy, refinements in risk classification have defined patients who do well with chemotherapy alone, and do not need HCT in CR1. Improvements in unrelated donor, cord, and haploidentical approaches have led to survival outcomes similar to those with sibling donor procedures, with hopes of further improvement in the near future when “targeted” donors will be chosen for immunologic advantage, decreasing relapse and toxicity risk.

Further refinements in the risk–benefit ratio of HCT compared with chemotherapy are likely, especially with a myriad of new agents coming forward that target pathways important in AML tumorigenesis and propagation. Concomitant with the development of targeted chemotherapeutic approaches to AML, both general and targeted immunologic approaches are being developed that show promise of improving outcomes. With this is mind, over the next decade we should anticipate an expanding repertoire of agents and approaches to deal with an increasingly subdivided group of diseases that are called AML. With still more than one-third of children eventually succumbing to this disease, there is room for new agents and approaches ultimately to improve the survival and quality of life of children with this challenging disease.

CHAPTER 52

Hematopoietic Cell Transplantation for Acute Lymphoblastic Leukemia in Adults

Stephen J. Forman
City of Hope Comprehensive Cancer Center, Duarte, CA, USA

This chapter is dedicated to the memory of my friend, colleague, and mentor, Karl G. Blume, MD.

Introduction

Acute lymphoblastic leukemia (ALL) is a hematologic malignancy of the bone marrow characterized by the rapid proliferation and subsequent accumulation of immature lymphocytes. ALL accounts for 20% of all acute leukemias in adults over the age of 20 years and affects approximately two persons per 100,000 in the United States annually. Over the past two decades, there has been substantial improvement in the understanding of the molecular biology of the disease and management of adult patients with this disorder. The success of therapy in children with ALL has continued to fuel the quest for similar success in adults utilizing the same principles that guide therapy in children, namely intensive induction and consolidation, maintenance therapy, and prevention of disease in extramedullary sites such as the central nervous system (CNS). Laboratory and clinical studies, including assessment of minimal residual disease (MRD) before transplant, can refine the decisions concerning the indication and timing of allogeneic hematopoietic cell transplantation (HCT). This chapter reviews the biology and treatment of adult ALL, the relationship of specific disease characteristics to the natural history of the disease, and the role of allogeneic and autologous HCT in the management of adult ALL patients.

Etiology

The cause of ALL in adults remains unknown and the associations are less distinct than they are with acute myeloid leukemia (AML) and are more closely identified with pediatric leukemia. For instance, in children with Down syndrome, there is an 18-fold higher incidence of childhood ALL than in the general population. In addition, there is an increased risk of ALL associated with inherited disorders such as Klinefelter syndrome, Fanconi anemia, Bloom syndrome, ataxia telangiectasia, and neurofibromatosis.

The incidence of acute leukemia, mainly AML, but also ALL, was increased almost 20-fold in survivors of atomic bomb explosions who were exposed to more than 1Gy of radiation. ALL can also occur after exposure to alkylating agents, epipodophyllotoxins, and other topoisomerase 2 inhibitors.

Signs and symptoms of disease

Patients with ALL generally present with signs and symptoms of uncontrolled growth of leukemic cells in the bone marrow, lymphoid organs, and other sites of extramedullary disease. The resulting bone marrow involvement results in varying degrees of anemia, thrombocytopenia, and granulocytopenia with manifestations of pallor, fatigue, petechiae, bleeding, and fever. Liver, spleen, and lymph node enlargement is common. ALL frequently involves organs other than the bone marrow and this spread is an important consideration in the treatment strategy. Many patients have extramedullary disease at diagnosis and extramedullary relapse is a known complication. The most common sites of extramedullary disease include the CNS, testes, lymph nodes, liver, spleen, and kidney, with the CNS and testes having the most clinical significance. The occurrence of extramedullary relapse after achievement of remission frequently heralds the development of a bone marrow relapse and requires systemic chemotherapy in addition to local treatment such as radiation (testes) or intrathecal treatment (CNS).

Clonal origin of leukemic lymphoid cells

Human ALL arises from a single progenitor cell that has undergone genetic damage leading to dysregulated growth and arrested differentiation. There is considerable evidence that each leukemic cell has descended from a single transformed progenitor as cytogenetic studies show common numeric and structural chromosome abnormalities within discreet leukemic cell populations. Uniform rearrangements of immunoglobulin (*Ig*) or T-cell receptor (*TCR*) genes, as compared with a more diverse pattern of rearrangements observed in populations of normal T- and B-lymphocytes, are further evidence of the clonal development. Additional evidence of clonality comes from studies by X chromosome-linked genes that are inactivated during embryogenesis and can be used to demonstrate the unicellular development of a leukemic cell population by detecting a single type of glucose-6-phosphate dehydrogenase in female patients. In addition, the methylation patterns of restriction fragment length polymorphisms in X-linked genes detected by Southern blot analysis can also be used to show the clonal evolution from a single transformed progenitor.

Lineage-specific features of leukemic lymphoblasts

Malignant lymphoblasts share many features of normal lymphoid progenitor development with rearrangements of the *Ig* or *TCR* genes. In many cases, the leukemic cells appear to represent a clonal expansion of a lymphoid progenitor cell that is blocked at an early stage of either B- or T-cell differentiation. Leukemic cells can be classified according to their normal developmental stage.

Mature B-cell ALL

The diagnosis of mature B-cell ALL depends on the detection of surface immunoglobulin on leukemic blasts. This rare phenotype accounts for only 2–3% of ALL cells and has distinct morphology (L3). It is important to diagnose this form of ALL accurately because most investigators believe that mature B-cell ALL is a disseminated form of Burkitt lymphoma, sharing cytogenetic, molecular genetic, immunologic, cytologic, and clinical features. For this type of ALL, responses and outcomes are better when treatment regimens are based on the treatment of Burkitt lymphoma that include rituximab, cyclophosphamide, and rapid rotation of antimetabolite drugs in high doses.

Pre-B- and early pre-B-cell ALL

Approximately 75% of ALL patients have lymphoblastic phenotype corresponding to those of B-cell progenitors. Within the B-cell lineage, the profiles of cell surface markers differ according to the stage of B-cell maturation. Pro-B-cell ALL accounts for about 10% of ALLs and is characterized by the presence of TdT, CD19, CD22, and CD79a, but negative for CD10 and other more mature B-cell markers. Approximately 50% of ALLs are positive for CD10 (the common ALL antigen or CALLA) and are termed CALLA-positive ALL. These cases frequently express CD19 and at least one other recognized B-lineage-associated antigen which includes CD20, CD24, CD22, CD21, and CD79 and also nuclear terminal deoxynucleotidyl transferase (TDT) or CD34. Approximately 10% of ALL express cytoplasmic Ig μ heavy-chain proteins but do not express surface Ig and are designated pre-B-cell ALL.

T-cell acute lymphoblastic leukemia

Leukemias of T-cell precursors are identified according to sequence of expression of T-cell-associated surface antigens during normal thymic ontogeny. The earliest T-cell precursors are characterized by the lack of expression of CD4 and CD8 surface markers, but these double-negative thymocytes express CD7, TDT, and cytoplasmic CD3 and proceed through a well-defined development, defined by the expression of CD44 and CD25. After this time, the *TCR* gene becomes rearranged and proceeds through a phenotype that is double negative to one that is double positive. This process is followed by the gain of CD3 expression and then the separation into mature CD4 and CD8 single positive cells. Similarly, T-cell ALL is frequently classified into early T-precursor ALL, expressing CD7 but not CD1a or CD3, thymic (or cortical) T-ALL, expressing CD1a but not cell-surface CD3, and mature T-cell ALL, expressing CD3. Thymic T-ALL makes up about 50% of T-ALLs and has the most favorable prognosis. In contrast to pre-B-cell ALL, the clinical features of T-cell ALL include high blood leukocyte counts, predominance in males, a higher incidence of CNS involvement, and radiographic evidence of a thymic mass in approximately half of the patients.

Mixed-lineage leukemia (ambiguous lineage)

Hematologic malignancies related to ALL include acute leukemias with ambiguous lineage, such as the mixed phenotype acute leukemias (MPALs). MPALs include bilineage leukemias in which two distinct populations of lymphoblasts are identified, with one meeting the criteria for AML, and biphenotypic leukemia in which a single population of lymphoblasts express markers consistent with B- or T-cell ALL, in addition to expressing myeloid or monocytic markers. To fulfill WHO criteria for an MPAL, the leukemic blasts must express myeloperoxidase and a strictly specific lymphoid marker. Many of these patients will have rearrangements of *BCR/ABL* or *MLL*. Treatment is guided by these findings [1].

Cytogenetic and molecular genetic analyses

In ALL, the multiple acquired genetic abnormalities are likely related to the malignant transformation and distorted cell growth and differentiation seen in ALL. These can include structural abnormalities detected by standard chromosomal analysis and molecular analysis of the DNA. Chromosomal translocations are found in many cases of ALL and are broadly classified as being recurring lineage-restricted abnormalities, accounting for two-thirds of the translocations, or random translocations or abnormalities of chromosome number. Figure 52.1 shows the frequency and distribution of major chromosomal abnormalities in patients with adult ALL [1]. In addition, the genes affected by chromosomal translocations are shown in bold face in the caption.

Cytogenetic abnormalities represent the strongest independent prognostic variables for predicting the outcome of treatment. In several multicenter studies, clonal chromosomal abnormalities could be detected in approximately 62–85% of patients, with the major abnormalities being clonal translocations (9;22, 4;11, 8;14, 1;19, 10;14) and also other structural abnormalities, including 9p, 6q, and 12p [2–4]. When there are no structural abnormalities

present, the abnormalities can be classified according to the modal number of chromosomes.

Molecular analyses are used to detect gene rearrangements in ALL by polymerase chain reaction (PCR), Southern blot analysis, or fluorescence in situ hybridization (FISH) utilizing chromosome-specific probes. The most frequent molecular markers in ALL are *BCR*/*AB*L and *ALL1*/*AF4*. The Philadelphia chromosome results from a translocation involving the breakpoint cluster region of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9 and can be demonstrated by molecular techniques. It occurs in about 25% of patients with adult ALL and increases with age. Approximately one-third of adult ALL with Philadelphia chromosome-positive (Ph$^+$) ALL showed a *BCR* rearrangement, resulting in a 210 kDa protein, similar to patients with chronic myelogenous leukemia (CML). Two-thirds, however, have an arrangement resulting in a 190 kDa protein. The most frequent form of 11q23 abnormality in ALL is the t(4;11) translocation. One partner gene is located on chromosome 11 and is named *MLL* for mixed-lineage leukemia. This gene is fused to a gene located on chromosome 4 that is named the *AF-4* and is frequently detected in infant leukemia and in patients with early pre-B subtype (CD10$^-$). The overall incidence of this chromosomal translocation in adults is 5%. Table 52.1 summarizes molecular aberrations in ALL with associated immunophenotypic, cytogenetic translocations, and clinical features seen in adults.

Treatment of ALL in adults

The treatment of ALL begins with a proper diagnosis and immunologic and cytogenetic characterization of the disease. Bone marrow aspiration and biopsy, and also lumbar puncture, are required for all patients. These are used both for evaluating prognostic features and disease monitoring and, in some circumstances, to determine specifics of therapy including the timing and indication for HCT. For patients with mature B-cell ALL, combination chemotherapy with rituximab has resulted in a high rate of remission and cure of the disease [5]. For patients with Ph$^-$ B- and T-cell ALL, chemotherapy is usually divided into several phases, beginning with remission induction, consolidation therapy, CNS prophylaxis, and maintenance treatment. Standard induction for therapy for B- and T-cell ALL includes prednisone, vincristine, and anthracyclines, mostly daunorubicin but also L-asparaginase. Other drugs such as cyclophosphamide and cytarabine (cytosine arabinoside, Ara-C) are added in many protocols. Prednisone and prednisolone have been the most frequently administered, although dexamethasone has a higher antileukemic activity in vitro and possibly better penetration into the CNS. Although the anthracycline dose intensity and schedule may play a role, many trials include a dose intensification with a 2–3-day schedule at the onset. Table 52.2 shows chemotherapy regimens commonly used in the treatment of adult ALL and the published response [6–10].

Table 52.2 Chemotherapy regimens for adult ALL

Study	Induction	Consolidation	CR (%)	Overall survival (%)
CALGB 8811 [6]	D, Pred, V, C, L-Asp	C, SC Ara-C, 6-MP, V, L-Asp, Dox, MTX, 6-TG, Dex	84%	50% (3-year)
Linker [7]	D, Pred, V, L-Asp	V, Pred, D, L-Asp, 6-MP, Ara-C, E, MTX	93	47 (5-year)
Hyper-CVAD [8]	C, V, Dox, Dex alternating with MTX, Ara-C	See "Induction"	92	38 (5-year)
UKALL/ECOG 2993 [9]	D, Pred, V, C, Ara-C, 6-MP	Ara-C, E, V, Dex, D, C, 6-TG	91	38 (5-year)
BFN [10]	D, V, Pred, L-Asp (phase I) C, Ara-C, 6-MP (phase II)	V, L-Asp, Dex (phase I) C, Ara-C, 6-TG (phase II)	83	35 (5-year)

ALL, acute lymphoblastic leukemia; Ara-C, cytarabine; BFN, Berlin–Frankfurt–Münster; C, cyclophosphamide; CALGB, Cancer and Leukemia Group B; CR, complete remission; D, daunorubicin; Dex, dexamethasone; Dox, doxorubicin; E, etoposide; ECOG, Eastern Cooperative Oncology Group; L-Asp, L-asparaginase; 6-MP, 6-mercaptopurine; MTX, methotrexate; Pred, prednisone; SC, subcutaneous; 6-TG, 6-thioguanine; UKALL, United Kingdom ALL; V, vincristine.

In addition, studies derived from childhood ALL, where the upfront therapy is curative in most patients, have also been explored in adults, with a suggestion of improved outcome. These and other studies that utilize pediatric-based regimens and schedules may provide a more effective treatment for patients up to age 35–50 years who are otherwise in reasonable health [2,11].

About 15–20% of adult patients do not achieve a complete remission (CR) after induction therapy compared with <3% of patients with childhood ALL. Although <10% of adult patients die during induction, the mortality is related to age, with the major cause of death being infection. Patients who fail to achieve a remission, analogous to those patients who are slow to achieve a remission and require two or more cycles of remission induction therapy, have a very poor prognosis and are candidates for early HCT [12]. Several studies have demonstrated that allogeneic HCT performed after failure to achieve CR can be curative in approximately 20% of patients [13–15]. Therefore, for adult patients, human leukocyte antigen (HLA) typing of the patient and family members is an important test to be performed early after diagnosis.

CNS prophylaxis

CNS leukemia occurs in about 6% of patients, with a higher incidence in T-cell ALL (8%) and mature B-cell ALL (13%). Treatment and prophylaxis of CNS leukemia usually consist of intrathecal methotrexate

(MTX) alone or in combination with Ara-C. Adult ALL patients who do not receive specific CNS treatment have a CNS relapse rate of 30%, similar to that observed in children. Therefore, all patients should receive some form of CNS therapy. In the past, prophylaxis often included CNS radiation to 24 Gy, which reduced the CNS relapse rate to about 9%. Most programs no longer include cranial radiation and utilize early systemic high-dose MTX and intrathecal therapy. The risk of CNS relapse is associated with other prognostic factors, including T- and B-cell ALL, extreme leukocytosis, elevated lactate dehydrogenase (LDH), and extramedullary organ involvement.

Management of CNS prior to HCT

In general, the development of a CNS relapse in patients with ALL portends a poor prognosis both for the effect it has on the CNS and because it is a harbinger of systemic relapse. Most patients with ALL have had some form of CNS prophylaxis with radiation or chemotherapy prior to their first systemic relapse. Adults with an isolated CNS relapse fare poorly and such an event is an indication for HCT [16]. Patients who relapse in the CNS require additional therapy to control the disease prior to HCT. Previous prophylactic intrathecal therapy and CNS radiation do not necessarily preclude the use of total body irradiation (TBI) in the preparation for HCT. However, if a patient has had CNS irradiation and relapses, a second course of irradiation prior to a TBI-containing preparative regimen is not recommended as it may lead to more neurotoxicity following transplantation. In general, these patients can be managed with either intrathecal MTX or the combination of MTX, Ara-C, and hydrocortisone until there is clearing of leukemic cells from the spinal fluid. Following HCT, such patients should receive five intrathecal MTX injections during the first 100 days followed by once-monthly injection for 12–18 months unless toxicity precludes additional treatments. This approach, designed in Seattle, can result in control of the leukemia without substantially increasing the risk of leukoencephalopathy [17]. The risk of CNS damage caused by cranial radiation, intrathecal chemotherapy, and high-dose chemotherapy has been documented and is related to the amount of intrathecal chemotherapy following the HCT procedure [17].

Currently, a common approach for patients with ALL who will be undergoing an HCT, without any evidence of prior CNS disease, is to administer intrathecal MTX as prophylaxis for a total of five times prior to the HCT procedure. Cranial radiation and post-transplant intrathecal therapy is not necessary if the patient then receives a preparatory regimen containing fractionated TBI.

Maintenance therapy

The optimal duration and form of maintenance therapy in adult ALL is unknown. The goal of maintenance treatment is to eliminate MRD that may have persisted after induction and consolidation treatment. Standard maintenance is usually based on a combination of 6-mercaptopurine and MTX. Attempts in previous trials to omit maintenance after induction and consolidation therapy resulted in inferior results.

In general, the cure rates with chemotherapy for adults with ALL are 35–40%. These results may be better in adolescents and younger adults utilizing more pediatric chemotherapy-based regimens and are poorer in older adults, especially over the age of 60 years [18,19].

Treatment of Philadelphia chromosome ALL

As noted above, t(9;22) is the most frequent genetic alteration in adult ALL, found in 20–30% of patients, and the incidence increases with age. The phenotype of this leukemia is almost exclusively CD10$^+$ precursor B-ALL and there are only rare reports of its presence in T-lineage ALL. Clinically, patients present with a variable white blood cell (WBC) count, surface expression of CD19, CD10, and CD34, and the co-expression of myeloid markers, especially CD13 and CD33. Cytogenetic and molecular genetic analyses are required to establish the diagnosis of Ph$^+$ ALL and can be obtained within 1 week of diagnosis. Historically, the prognosis of adult patients with Ph$^+$ ALL treated only with chemotherapy has been poor, with less than a 10% probability of long-term disease-free survival (DFS). Complete remission rates after induction therapy range from 60 to 90%; however, the median remission duration was inferior, between 9 and 16 months. The disease has been even more difficult to treat in older patients with ALL, where this cytogenetic abnormality actually is more common.

The understanding of the leukemogenic role of the *BCR/ABL* oncogene and its dependence on the constitutive activation of the *ABL* tyrosine kinase led to the development of selective *ABL* inhibitors, with imatinib being the first to gain clinical approval. Its initial activity was demonstrated in phase I and II trials in CML, but also in ALL. When treated with imatinib as a single agent, many patients with Ph$^+$ ALL achieved a remission, but there were no long-term survivors. Only the subset of patients who then went to allogeneic HCT while in remission had a favorable outcome, with 50% of the patients disease free at 1 year [20]. The limitations of single-agent imatinib led to various investigations to explore the efficacy of imatinib as front-line therapy in combination with chemotherapy. Phase II trials combining imatinib or dasatinib (days 1–14 of each cycle), with hyper-CVAD (fractionated cyclophosphamide, vincristine, adriamycin, and dexamethasone) chemotherapy had a very high remission rate after 21 days of treatment, suggesting synergy between imatinib and concurrent chemotherapy, with some patients achieving a molecular remission [21,22]. Similarly, encouraging results have been achieved in other centers in which imatinib was started after 1 week of induction therapy and then coadministered with chemotherapy during the remaining induction. In these trials, the 1-year event-free survival (EFS) and overall survival (OS) were 78–88% with tolerability comparable to that seen with chemotherapy alone. Both alternating and concurrent imatinib chemotherapy combinations have been studied, with a clear advantage of the simultaneous over the alternating schedule in terms of the achievement of a negative PCR for the *BCR/ABL* gene [23]. Those patients who undergo allogeneic HCT for ALL do not seem to have any detrimental effect of prior imatinib treatment.

Given the increased incidence of Ph$^+$ ALL in older patients with ALL and the difficulty of achieving a remission in these patients, imatinib has also been studied as front-line treatment in older patients with ALL, with an improved outcome compared with chemotherapy and with better tolerability [24]. Several studies now suggest that imatinib combined chemotherapy in newly diagnosed Ph$^+$ ALL with subsequent treatment with allogeneic HCT has improved the results of treatment. With regard to the CNS, patients with Ph$^+$ ALL are at significant risk for developing CNS leukemia [25]. Imatinib concentrations in the CSF reach about 1–2% of serum levels and are not therapeutic. hence all patients with ALL, independent of their chromosome abnormality, require CNS prophylaxis. Additional novel tyrosine kinase inhibitors with significantly more potent activity against the *BCR/ABL* gene are now available. Nilotinib has recently been tested in combination with chemotherapy in newly diagnosed patients with encouraging results [3,4]. As discussed below, the use of these drugs may have an impact on the pre-transplant disease burden of the patient and reduce the risk of relapse following HCT.

Prognostic factors in ALL

The major prognostic factors for achieving a CR are advanced age and, historically, Ph^+ ALL, although this has now changed with the use of tyrosine kinase inhibitor (TKI) drugs as part of induction therapy. Prognostic factors are of even greater importance in predicting the durability of remission and survival and are utilized to assess the need for allogeneic HCT. Table 52.3 identifies some of the adverse prognostic factors for remission duration in adult ALL that have been identified in previous clinical trials and are utilized in determining a patient's risk of relapse.

Role of minimal residual disease

In addition to age and cytogenetic analysis at the time of diagnosis, the most important prognostic factor, and a direct reflection of sensitivity to chemotherapy, is the rapid achievement of CR. Thus, a slower time to achieving a remission is an indicator of relative chemoresistance, similar to what has been observed in pediatric patients. Those patients who take more than one cycle of induction chemotherapy have a poor long-term prognosis and shorter remission duration [6,9,10].

A more quantitative approach to assess the response of an individual patient to chemotherapy is the measurement of minimal residual disease at various time points after therapy. Quantitative assessment of tumor cell kill has emerged as an independent prognostic factor that reflects the resistance of the cells to chemotherapy and may allow individualization of treatment [16,26,27]. The assessment allows the identification of potential patients at high risk for relapse despite achieving a morphologic remission and who may benefit from early HCT. At present, there are ongoing efforts to standardize MRD quantitation using real-time quantitative PCR of clonal immunoglobulin and *TCR* gene rearrangements, fusion gene transcripts or breakpoints, and multiparameter flow cytometric immunophenotyping (see Chapter 25 for a more complete discussion of the MRD measurement of utility). It remains to be determined what the benefit of HCT may be in patients who are in first remission, but have evidence of this new factor defining high-risk disease, that is, high MRD, compared with those patients who are MRD negative at the time of transplant. Hence the future of treatment of adult patients with ALL in first remission will be refined to determine those patients who are unlikely to benefit from further chemotherapy and should be considered for transplantation during first remission and those likely to do well with continued chemotherapy [28]. The detection of MRD at the completion of therapy also has implications for the success of transplant when patients with detectable MRD have a greater chance of relapse than those patients who are MRD negative [14]. An additional important question is whether MRD-positive patients should receive additional therapy pre-transplant in order to reduce the disease burden. Monitoring MRD in patients after transplantation in order to treat prior to overt relapse may also become a useful practice.

Table 52.3 Clinical and laboratory risk factors for adult ALL

Risk factor	Prognosis association
At presentation	
Age	Continuous variable; adverse outcome with advancing age
CNS involvement	Adverse outcome
Presenting WBC count	Adverse for B-cell phenotype: >30 × 10^9/L Adverse for T-cell phenotype: >100 × 10^9/L
Immunophenotype	Adverse with CD20 expression
Cytogenetics	Adverse: t(9;22); t(4;11); complex (>5 abnormalities); low hypodiploidy, near tetraploidy Favorable: high hyperdiploid; del 9q
Molecular abnormalities	Adverse: JAK2; IKFZ1; PAX5; TLX3; ERG; BAALC Favorable: TLX1
In response to therapy	
Time to initial response	Adverse: failure to attain CR within 4 weeks of induction (variably demonstrated among studies)
Detection of MRD	Adverse: detection at various time-specific points in several studies

Allogeneic HCT in first complete remission of ALL

Allogeneic HCT in first CR has generally been reserved for those patients who present with poor risk features, such as those described earlier. In several phase II studies, patients with high-risk disease treated with allogeneic HCT had a DFS longer than would have been predicted, especially those with Ph^+ ALL. Studies have been conducted that indicate that HCT offers some groups of high-risk patients long-term disease survival rates of between 40 and 60%. At Stanford University, a series of patients with high-risk features underwent full-intensity allogeneic HCT in first CR included patients with WBC >25,000/μL, chromosomal translocations t(9;22), t(4;11), and t(8;14), age >30 years, extramedullary disease at the time of diagnosis, and/or requiring more than 4 weeks to achieve a CR. Two-thirds of the patients had at least one risk factor and the remaining patients had two or more high-risk features at presentation. The majority of these patients underwent allogeneic HCT within the first 4 months after achieving a CR. At a median follow-up of >5 years, the probability of EFS was 64% with a relapse rate of 15% [29] (Figure 52.2).

Postremission therapies: matched-sibling HCT versus chemotherapy or autologous HCT

There have been several prospective studies that have reported patient outcomes after a variety of postremission therapies, with or without a family donor, who could then proceed to transplant (Table 52.4). Some of these studies also compared matched-sibling HCT versus chemotherapy or autologous HCT. Ribera et al. analyzed 83 Ph^- ALL patients in CR1 (eligibility age, 15–50 years) and failed to demonstrate that having a family donor available for allogeneic HCT provided superior outcomes compared with chemotherapy or autologous HCT [30]. The reported relapse rate of 62% at 5 years in the donor group, however, seemed surprisingly high in patients transplanted in first remission. The MRC UKALLXII/ECOG 2993 study was designed to determine the impact of transplant in first remission on relapse and survival [31,32]. The trial enrolled patients aged 15–64 years, but 59 years was the upper age limit for allogeneic HCT recipients. Using a donor versus no-donor analysis, they showed that Ph^- ALL patients with a donor had an improved 5-year OS (53% vs. 45%, $p = 0.01$) and an associated significantly lower relapse rate ($p < 0.001$) (Figure 52.3). The survival difference was significant in standard-risk patients, whereas in high-risk (especially older) patients, the reduced relapse risk was offset by an increase in non-relapse mortality (NRM). In this large study, subjects randomized to chemotherapy had a better 5-year OS (46%) than those randomized to autologous HCT (37%, $p = 0.03$), demonstrating no benefit for a single autologous HCT. Cornelissen et al., for Hemato-Oncologie voor Volwassenen Nederland (HOVON), reported on two consecutive, prospective studies of myeloablative (MA) HCT in ALL CR1 patients aged 15–55 years, similar to the MRC UKALLXII/ECOG

trial described above [33]. They showed significantly better 5-year DFS in the donor group (60% vs. 42%, $p = 0.01$). As expected, NRM was significantly higher in the donor group (16% vs. 3%, $p = 0.002$), but those patients with a donor had a markedly lower incidence of relapse at 5 years (24% vs. 55%, $p < 0.001$), confirming the improved disease control for patients undergoing transplant. As in the MRC/ECOG study, the benefit was most pronounced in the standard-risk group, although in this study poor-risk patients in the donor group also had a significantly improved outcome. Kako et al., for the Japan Adult Leukemia Study Group (JALSG), analyzed two JALSG studies (ALL93 and ALL97) in order to identify the optimal strategy of postremission therapy in Ph$^-$ ALL CR1 patients who had an HLA-matched sibling in patients aged 15–54 years [34]. In their analysis, allogeneic HCT was superior to other therapies, with a 10-year survival probability of 48.3% versus 32.6%, respectively.

Overall, these studies suggest that allogeneic HCT is more effective than chemotherapy or autologous HCT for control of leukemia in Ph$^-$ ALL CR1 patients. The statistically significant survival advantage, however, appears to be greater for standard-risk than high-risk ALL patients, especially if MRD positive after induction [5] mostly related to the impact of age on outcome, a finding that likely reflects the increased treatment-related mortality (TRM) in the high-risk group that negated the graft-versus-leukemia (GVL) effect in these patients.

HCT for Philadelphia chromosome-positive ALL

Historically, the dismal outcome with chemotherapy has led to trials focusing on the use of allogeneic transplantation for treatment of adult Ph$^+$ ALL. Most have been single-institution studies utilizing a variety of regimens and the cure rate varies from 30 to 65%, dependent upon age and remission status [35,36]. Investigators from City of Hope and Stanford University analyzed their experience in 79 patients with Ph$^+$ ALL transplanted from HLA-identical siblings while in first CR between 1984 and 1997 to determine long-term survival and disease control [37]. All patients but one were conditioned with fractionated total body irradiation (FTBI) (1320 cGy) and high-dose etoposide (60 mg/kg). The 3-year probability of DFS and relapse was 55% and 18%, respectively ,with the latest relapse at 27 months. Beyond first remission, HCT is curative in a much smaller minority of patients but remains the treatment of choice (Figure 52.4).

The development of imatinib and dasatinib for the treatment of *BCR/ABL*-positive hematopoietic malignancy has changed the upfront treatment strategy and outcome and may also affect the outcome after HCT. Dasatinib is a second-generation TKI that has enhanced potency against the BCR/ABL protein and the ability to block the SRC family of kinases. In a clinical trial of Ph$^+$ ALL, newly diagnosed patients with Ph$^+$ ALL were treated with hyper CVAD and dasatinib 100 mg/day; 94% achieved a CR and the 2-year survival was 64%. The feasibility of performing allogeneic HCT after first-line treatment with imatinib plus chemotherapy has also been reported [38,39]. In one series, 29 adult patients who completed induction therapy were treated with allogeneic HCT and the authors compared their results with those for 31 patients who had received transplantation in their unit prior to the availability of imatinib treatment. The data suggest that the risk of relapse was significantly less in the imatinib group (3.5% vs. 47.3%, ($p = 0.002$), potentially reflecting a lower burden of residual disease at the time of HCT and allowing a higher percentage of patients to come to transplantation in a low MRD first remission. The results also indicated

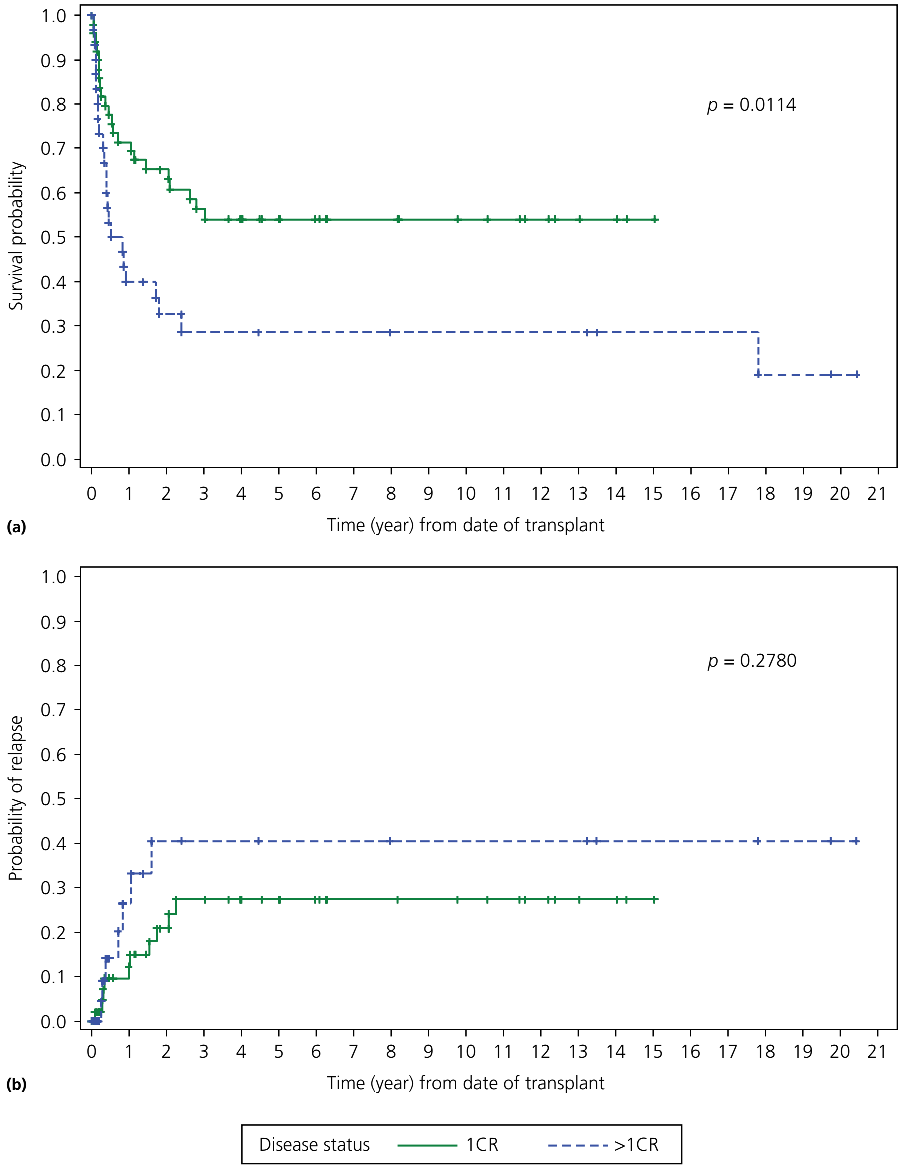

Figure 52.4 Probability of long-term (a) disease-free survival and (b) risk of relapse in 79 patients with Ph$^+$ ALL following allogeneic HCT in first remission and beyond first remission Source: Laport et al. 2008 [37]. Reproduced with permission of the American Society of Hematology.

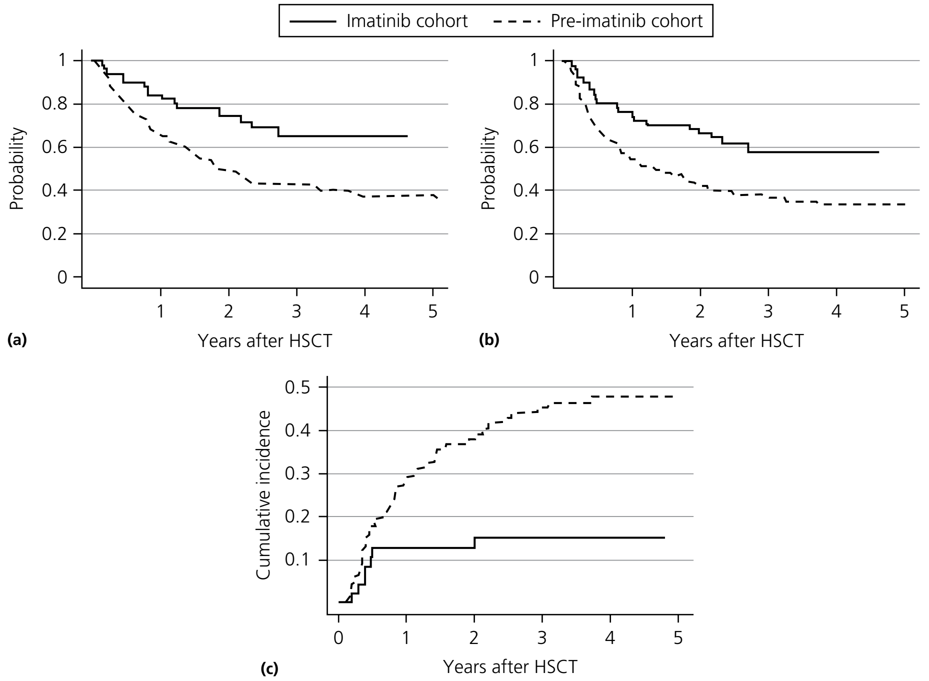

Figure 52.5 Transplantation outcomes of 51 patients who received imatinib-based therapy and 122 historical patients. (a) Overall survival, (b) disease-free survival, and (c) cumulative incidence of relapse. Source: Mizuta et al. 2011 [39]. Reproduced with permission of Nature Publishing Group.

superiority in DFS (76% vs. 38%, $p < 0.001$) without much difference in the transplant-related toxicities. In the second series of patients, the probability of OS, DFS, and relapse were improved in these patients who received pre-transplant imatinib (Figure 52.5) [39]. Thus, in the same way that imatinib may improve the upfront success of induction therapy and potential long-term outcome of patients with Ph^+ ALL, entering transplantation with lower burden of disease may improve the cure rate for such patients [38,39]. Currently, a national trial comparing hyper-CVAD and dasatinib with allogeneic transplant followed by post-transplant dasatinib to determine the best upfront approach for patients with Ph^+ ALL has been completed.

Relapsed or primary refractory ALL

ALL is refractory to primary chemotherapy in approximately 10–15% of patients and allogeneic HCT can be successfully used to achieve both remission and long-term control in approximately 20% of such patients and should be considered when patients fail to achieve a CR after the first course of intensive induction therapy treatment. Of all those patients who do achieve a first CR to primary therapy, approximately 50–70% will relapse. Relapsed ALL in an adult is not curable with standard chemotherapy, but remissions are sometimes achieved with reinduction using either a standard vincristine, prednisone, and anthracycline regimen or with a cytarabine-based regimen, particularly high-dose Ara-C (HDAC) combined with an anthracycline or clofarabine, especially in patients with a long first remission [40]. Many studies have confirmed that in the absence of HCT, adult patients with relapsed ALL have an extremely poor prognosis regardless of initial remission duration, and that transplantation, when feasible, is the only possible curative therapy [41]. Available data from the Center for International Blood and Marrow Transplant Research (CIBMTR) show that patients transplanted using an HLA-identical sibling donor for ALL in CR2 have approximately a 35–40% chance of long-term DFS, whereas those transplanted with disease not in remission have a DFS of only 10–20%. Figure 52.6 shows the overall DFS for patients with ALL who were able to achieve a second remission, had a donor, had no major contraindications, and underwent allogeneic HCT. As in all series, these data do not account for those patients who suffer a relapse and do not undergo transplantation, which represents the majority of patients [42]. When accounting for all patients with relapsed ALL, the overall cure rate for such patients is much less than 20%. There is an urgent need for new medicines that can be used as a bridge to transplant, the most promising of which are bispecific engaging antibodies to CD19 (blinatumomab) drug immunoconjugates such as inotuzumab, and SAR 3419, CD19-specific chimeric antigen receptor (CAR) transduced T cells and ponatinib for patients with refractory Ph^+ ALL. Nevertheless, for an

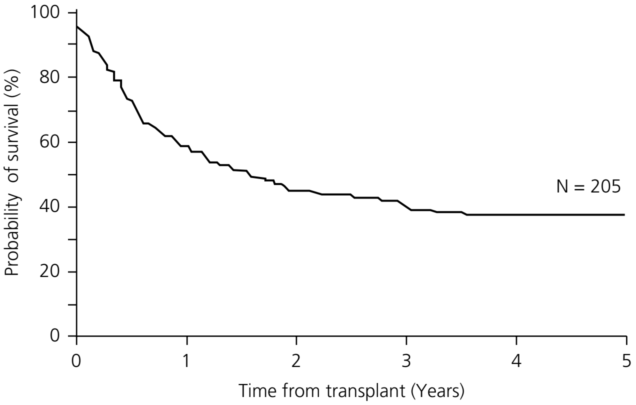

Figure 52.6 Disease-free survival of patients undergoing allogeneic transplant while in second complete remission. Source: Forman and Rowe 2013 [42]. Reproduced with permission of the American Society of Hematology.

adult patient with ALL after a first relapse, therapy that facilitates treatment with an allogeneic HCT is the best curative option.

Unrelated donor HCT for ALL

Historically, the outcome after transplantation from unrelated donors has been inferior to that observed after matched-sibling transplantation because of increased rates of graft rejection and graft-versus-host disease (GVHD) resulting from increased alloreactivity in this setting. Over the past few years, improved results have been reported from several single-center studies, reflecting improvements in donor–recipient allele level molecular matching in both class I and II histocompatibility genes, GVHD prophylaxis, and supportive care, especially prevention of viral and fungal infections. Published reports suggest equivalent overall survival results for patients with Ph^- ALL undergoing transplant in first or subsequent remission with the risk of relapse being lower in patients receiving transplant from an unrelated donor [43–45], making this a very reasonable option for patients who need an allogeneic HCT for treatment of their disease, but do not have a sibling donor.

Role of GVL effect in patients with ALL

The low response rate in patients with ALL following donor lymphocyte infusion (DLI) has led to questions about the significance of the GVL effect in preventing relapse in this disease. The GVL effect is derived from observations of a higher relapse rate after autologous or syngeneic HCT compared with allogeneic HCT, lower incidence of relapse in patients who had GVHD, and increased relapse rates in recipients of T-cell-depleted marrow grafts. The most compelling argument for a strong GVL effect in ALL comes from both single-institution and registry data [46–48]. These studies show a consistent decrease in relapse rates in patients who develop GVHD compared with those who do not. Table 52.5 shows the rate of relapse after HCT for ALL in CR1 and the correlation with GVHD. The occurrence of acute, chronic, or both forms of GVHD correlated with the best DFS. A subsequent study in 182 patients suggested a potential GVL effect in patients who were not in remission at the time of transplant [49]. Studies have also demonstrated the beneficial impact of chronic GVHD on reducing relapse in patients undergoing allogeneic HCT for ALL, including Ph^+ ALL [50,51].

Although the data support the importance of a GVL effect in mediating a clinically useful antileukemic response in patients with ALL, the reasons for the limited beneficial effect for patients with relapsed ALL treated with DLI are not clear. Nonetheless, cytoreduction with chemotherapy prior to infusion of DLI is a better strategy for patients with relapsed ALL. It is for these reasons that HCT after reduced-intensity conditioning (RIC) is of limited effectiveness in patients with ALL who are not in remission. Studies focused on developing CD19-specific CAR transduced T-cell immunotherapy for ALL may help augment the GVL activity of donor T cells (see Chapter 69).

Table 52.5 Relapse after transplantation for ALL in CR1 [47]

Group	Relapse probability at 3 years (%)
Allogeneic, non-T-depleted	
No GVHD	44 ± 17
Acute only	17 ± 9
Chronic only	20 ± 19
Both	15 ± 10
Syngeneic	41 ± 32
Allogeneic, T-depleted	34 ± 13

HCT after reduced-intensity conditioning for treatment of ALL

There have been only a limited number of studies of RIC in patients with ALL. In general, the consensus has been that for patients with ALL, high dose chemoradiotherapy was required for an improved cure rate, but this approach is of limited use in patients over the age of 50 years. In addition, an evaluation of outcomes suggests that the graft-versus-tumor effect is more effective against myeloid malignancies such as AML and CML and B-cell malignancies of mature B cells such as low-grade non-Hodgkin lymphoma, chronic lymphoid leukemia (CLL), and multiple myeloma, but less so with a more undifferentiated B-cell disease such as pre-B-cell ALL, especially if not in remission [52,53] (see Chapter 16). Nevertheless, an increasing number of small studies have been conducted that suggest that there is a role for reduced-intensity allogeneic transplant even in this disease, particularly in older patients, with 34% achieving long-term remission in a report from the European Group for Blood and Marrow Transplantation (EBMT) [52]. A report of patients undergoing HCT utilizing either a related, unrelated ,or cord blood donor and a fludarabine/melphalan or clofarabine/busulfan-based regimen showed optimistic outcomes in a group of patients either at high risk during first remission or who were transplanted after achieving a second or subsequent remission [54]. Table 52.6 shows the outcome for several series of patients with ALL undergoing reduced-intensity transplantation with regimens of varying intensity with DFS ranging from 38 to 63% with only 50% of patients receiving this therapy in CR1 [16,55–62]. Patients with Ph^+ ALL who received post-transplant imatinib showed a DFS of 62% [62]. The results of the recent UK ALL XII ECOG 2993 study of adult ALL show high toxicity and limited improvement in DFS despite better disease control in older adult patients. Hence there is increased interest in the development of clinical trials exploring these reduced-intensity approaches in older patients with ALL in remission who would otherwise be candidates for transplantation based on age, cytogenetics, MRD, and response to initial treatment. The poor outcome of older patients

Table 52.6 Reduced-intensity transplant outcomes for ALL

Study	Patients	TRM/NRM	Relapse	Survival

with ALL using standard chemotherapy makes this an important consideration for treatment in those patients.

Regimen development for allogeneic HCT for ALL

Historically, the most commonly used ablative regimen for transplantation of patients with ALL is cyclophosphamide (CY) combined with FTBI. Several other preparative regimens have been developed, each based on substituting a different chemotherapeutic agent for CY in combination with TBI for patients with ALL.

Investigators at Johns Hopkins University approached the problem by substituting busulfan (BU) for TBI in order to decrease the long-term side-effects of TBI [63,64]. These non-radiation-dependent regimens have shown activity in the treatment of advanced ALL, demonstrating that TBI is not an absolute requirement for successful treatment of ALL by HCT. A retrospective analysis from the CIBMTR found that a conventional CY/TBI regimen was superior to a non-TBI-containing regimen of BU plus CY in children, with a 3-year survival of 55% versus 40% for BU/CY [65]. However, despite these differences in survival, the risk of relapse was similar. Studies of BU, fludarabine and 400 cGy of TBI showed a low transplant-related mortality of 3% and a projected DFS of 65% [66].

The group at the City of Hope studied the substitution of etoposide (VP16) for CY in combination with FTBI (13.2 Gy) followed by allogeneic HCT [67]. A phase I/II trial indicated that a VP16 dose of 60 mg/kg is the maximum tolerated dose when combined with a TBI dose of 1320 rad. In that study, 36 patients with ALL were treated, 20 of whom were in relapse. The actual DFS was 57% with a 32% relapse rate, suggesting that the regimen had significant activity in patients with advanced ALL, a result confirmed in a subsequent trial from the Southwest Oncology Group [68]. A subsequent study from City of Hope/Stanford showed a 64% DFS for adult patients undergoing transplantation with this regimen in CR1 (see the section on allogeneic transplant for ALL in first remission). The UK ALL XII/ECOG 2993 trial, a comparative study of chemotherapy and autologous and allogeneic HCT, utilized this regimen for patients in CR1.

A comparative analysis of TBI combined with either cyclophosphamide or etoposide chemotherapy was conducted to determine the relative efficacy of chemotherapy in the radiation-based transplant regimen and suggested that when the TBI dose was >13 Gy, the results are the same for TBI/CY and FTBI/VP16 [69]. Transplant-related mortality did not differ by conditioning regimen.

Management of relapse after allogeneic transplant for ALL

If patients with ALL relapse after HCT, the prognosis is very poor. Similarly to the approach for patients with AML and CML, manipulation of the antitumor effect mediated by the donor graft is often employed as a treatment strategy. Unfortunately, in patients with ALL, this therapy has not been as effective as it has been for patients with other hematologic malignancies. In a report from Europe, 40 patients with ALL received DLI as treatment for relapse and of 29 evaluable patients, only one achieved CR [70]. Therefore, DLI as a sole therapy appears to have low potential for contributing to remission and long-term control of disease in patients with relapsed ALL and, if considered, should be a component of a chemotherapy-based treatment program. For those patients with Ph^+ ALL, imatinib or dasatinib, either alone or with chemotherapy, is effective in helping some patients achieve another remission, although the duration of the remission is often fairly short and DLI should be performed before another relapse occurs. The role of donor-derived CAR transduced CD19-specific T cells is also being explored as a treatment for relapse after transplant [6]. Remissions have also been achieved following relapse utilizing a CD19 BiTE antibody without inducing a flare of GVHD [7].

Autologous HCT for adult ALL

There is much less experience with autologous transplantation for ALL and studies have been focused primarily on those patients in either first or second remission who lacked a sibling or unrelated allogeneic donor. Several groups have reported outcomes for large series of adults with ALL undergoing autologous HCT in first remission [71]. The most important prognostic factor was the interval between achieving a CR and proceeding to transplant, with those patients being transplanted later having the better DFS, but no real improvement over the results achieved with chemotherapy. This effect may represent the dropout of high-risk patients who relapse before transplantation or possibly the effect of consolidation therapy in reducing tumor burden administered prior to HCT. The European Cooperative Group/MRC report on over 1000 patients indicated a leukemia-free survival (LFS) of 36% and the CIBMTR reported a similar plateau at 40%.

One randomized trial evaluated outcomes of adults with ALL in first remission treated with chemotherapy versus autologous transplantation. The French LALA 87 trial allocated patients under 40 years of age with HLA-matched siblings to allogeneic transplantation whereas the remaining patients received consolidation treatment with modest dose chemotherapy or an autologous transplant. There was a significant dropout rate in the autologous arm due to early relapse and the long-term follow-up showed no significant difference in OS between the two groups: 34% for autologous HCT and 29% for chemotherapy. This lack of difference applied to both the standard-risk and high-risk groups. A large trial involving collaboration between the Eastern Cooperative Oncology Group (ECOG) and the MRC reported the outcome comparing allogeneic transplant, autologous transplant or chemotherapy in all adult patients with ALL in first remission and showed an inferior result for autologous transplantation versus continued chemotherapy.

Cell sources for HCT

As is true for most patients undergoing allogeneic transplantation, peripheral blood has replaced bone marrow as the hematopoietic cell graft preference. A report from the EBMT retrospectively compared the outcome of 858 patients, 513 who were in first remission given marrow, with 345 patients who were given blood. Peripheral blood, as noted in many studies, resulted in faster engraftment but also in an increased risk for chronic GVHD. Recent reports from the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) trial showed that in patients undergoing an ablative transplant, relapse was equivalent between patients receiving blood or marrow, but chronic GVHD was higher in those patients receiving blood [72]. In this series, there was no obvious difference in survival or relapse, but the increased incidence of chronic GVHD in patients who received peripheral blood as the stem-cell source should be factored into the decision regarding which source of cells to utilize.

Umbilical cord transplantation

There has been considerable interest in exploring the potential of umbilical cord transplantation, but there are less specific data in patients with ALL. In a CIBMTR study of 1525 patients, a comparison was made between hematopoietic cells derived from umbilical cord transplant and an unrelated donor following high-dose conditioning, which resulted in comparable outcomes [73]. Several studies have now reported the results of unrelated cord blood grafts, with outcomes similar to those with unrelated adult donor-derived stem cells, but with different patterns of treatment failure [74,75]. In one study of reduced-intensity transplantation, there were only 16 adult patients with ALL and the diagnosis of ALL predicted a high risk for relapse [56]. At present, the data suggest that this cell source is acceptable for transplant where an unrelated donor cannot be identified and there is an adequate CD34$^+$ cell dose in the cord blood [8,9].

Haploidentical transplantation

Haploidentical-related donor transplantation is being evaluated in patients with a variety of hematologic malignancies and has shown promise, especially with the use of post-transplant cyclophosphamide to reduce the alloreactivity of donor T cells. To date, there are limited data about the outcomes in patients undergoing haploidentical transplantation for treatment of ALL [10,11]. In the context of a clinical trial, this would be an option in a patient lacking a suitable matched related, unrelated, or cord blood donor source of stem cells.

Treatment strategy for ALL

As discussed in this chapter, advances in molecular genetics and clinical treatment outcomes have resulted in more refined recommendations concerning the timing of transplantation for patients with ALL. Most studies indicate that allogeneic transplantation in first remission provides a better chance of DFS, especially in younger patients with high-risk disease where the risk is related to the leukemia cell and its response to treatment (MRD positive). For patients who are younger than 50 years without other high-risk features, intensive pediatric-type chemotherapy programs may offer an option for successful treatment, reserving transplantation for those patients who do not achieve a molecular CR. For patients who relapse, transplantation is the only treatment with the potential for cure, especially if a second remission can be achieved. Therefore, it is important to perform HLA typing at the time of diagnosis to determine what the transplant possibilities might be either from related donors or through the unrelated donor registries, especially for patients with high-risk features such as high WBC count, older age, slow rate of achieving remission, or failure to achieve a remission, or when there is detection of MRD either early or emerging late in treatment. In addition, this information would be useful in planning for treatment in patients who suffer a relapse after achieving a remission. Identification of the Philadelphia chromosome early after diagnosis gives patients an additional beneficial therapeutic option with the inclusion of TKIs as part of the induction, consolidation, and maintenance regimen. Trials are ongoing that will compare the outcome of this modern approach to ALL along with a more modern approach to ALL following transplantation. Figure 52.7 provides a suggested algorithm for the use of transplantation in adult patients with ALL.

Figure 52.7 Suggested treatment and transplant algorithm for adult patients with ALL.

Future considerations

For a number of years, there were few, if any, innovations in the treatment of ALL in adults, especially in the development of new agents. However, over the last few years, a number of agents, including monoclonal antibodies to CD20, CD52, and CD22 and new drugs for T-cell ALL such as nelarabine and TKI drugs imatinib, dasatinib, and nilotinib for the treatment of Ph^+ ALL may improve the treatment outcome for patients with ALL. In addition, the development of novel immune-based approaches, including CD19-specific CAR T cells to treat relapse, is now being tested as part of upfront therapy in the setting of allogeneic or autologous transplant. Blinatumomab and drug immunoconjugates are being developed that may serve as a more effective bridge to transplant and lower MRD at the time of transplant and are being explored as part of the upfront management.

The most important contribution may come from studies defining which patients are most likely to benefit from transplantation early in the course of their disease. Thus, the monitoring of MRD may have a predictive value for relapse, as a reflection of sensitivity to chemotherapy. This would be an important development for all patients. Those patients, even those with higher risk disease, who achieve a CR with lack of detection of MRD may be spared the risk of transplantation whereas other patients, even those with low-risk disease, who have not achieved an adequate depth of remission would be better served by early transplantation, even if there were no overt high-risk features at the time of diagnosis. Thus, introduction of MRD monitoring over the course of treatment might provide a new strategy for how to advise patients about the timing of transplantation. Some investigators believe that MRD measurement, as a reflection of sensitivity to therapy, may substitute for all other prognostic features once a patient achieves a remission [27].

In addition, transplantation regimens are being developed to address patients with high-risk disease that could include radioimmunotherapy targeted to the CD45 antigen and the use of marrow-based radiation therapy techniques to augment the radiation dose that can be delivered to the marrow. Studies are also being conducted to determine the efficacy of utilizing antigen-specific T cells to augment a graft-versus-tumor effect. These cells can be derived from normal donors and could be transduced to recognize the CD19 antigen present on nearly all patients with pre-B-cell ALL. Finally, given the results of chemotherapy treatment of older patients with ALL, studies of RIC should be pursued for such patients in order to explore the potential therapeutic role of GVL effects in this high-risk patient population.

CHAPTER 53

Hematopoietic Cell Transplantation for Acute Lymphoblastic Leukemia in Children

Parinda A. Mehta and Stella M. Davies
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Introduction

Acute lymphoblastic leukemia (ALL) of childhood includes a heterogeneous group of disorders, each with differing molecular genetic abnormalities and clinical behavior. Significant advances in chemotherapy regimens have been made over the last 50 years, such that more than 80% of children with ALL are now cured with chemotherapy [1–7].

The remarkable progress achieved in the treatment of childhood ALL is the result of series of large-scale clinical studies conducted by cooperative clinical trials groups. In addition, biologic investigations have led to improvements in risk group identification and allowed the administration of risk-adapted therapy, improving the results of clinical trials. These advances in chemotherapy treatment have occurred in parallel with important changes in transplantation techniques, donor availability, and supportive care in hematopoietic cell transplantation (HCT). Together, these events have led to changes over time in indications for, and outcome of, HCT for childhood ALL. The indications for HCT in childhood ALL are likely to continue to change in future years as advances are made in chemotherapy, HCT, and understanding of biology.

This chapter reviews the genetic characteristics of childhood ALL, which are central to accurate risk assessment, and discusses the biologic differences between childhood and adult ALL. Outcomes of sibling donor HCT are reviewed, followed by a discussion of the selection of conditioning regimens. For the majority of patients who have no available sibling hematopoietic cell donor, the use of alternative hematopoietic cell sources is an important therapeutic option, and outcomes of mismatched related marrow, unrelated marrow, and umbilical cord blood (UCB) donor transplants are reviewed. Two particular pediatric populations, infants with ALL and children with Down syndrome and ALL, require special consideration, and the appropriate use of HCT in these cases is discussed. Finally, data regarding the effectiveness of management of relapse after HCT with a second transplant are presented.

Diagnosis and classification of ALL in childhood

The last 25 years have seen an explosion in our knowledge of the phenotypic and genotypic characteristics of childhood ALL. The advent of monoclonal antibodies allowed the characterization of cell surface phenotypes of childhood ALL, and now categorization of leukemia according to cell of origin is routine. Immunophenotyping demonstrates that most cases of childhood ALL are B lineage, while the remainder are T lineage (Table 53.1) [8]. B-lineage leukemias generally arise early in B-lymphocyte development before the maturation of surface immunoglobulin, and are termed "B precursor ALL." Cases with cytoplasmic immunoglobulin are termed "pre-B ALL." Cases with similar pre-B surface markers that do not express cytoplasmic immunoglobulin are termed "early pre-B ALL" [9]. Some mixed lineage phenotypes (expressing lymphoid and myeloid markers) have been observed. The association of B-cell and monocyte markers is especially important in childhood leukemia because it is seen frequently in the high-risk leukemias that arise in infants [10].

While immunophenotyping allows the categorization of ALL by cell of origin, the development of molecular genetics has allowed for a finer classification of ALL into prognostically important subgroups on the basis of acquired genetic abnormalities. A large number of specific genetic alterations, commonly but not always associated with specific chromosomal translocations, have been described (summarized in Table 53.1), and are important predictors of outcome of chemotherapy. Some genetic abnormalities appear to be the consequence of mistakes in the normal process of DNA rearrangement used to generate immunologic diversity in lymphoid progenitor cells, as shown in Table 53.1. Examples include leukemias that involve immunoglobulin or T-cell receptor rearrangements. The functional result of such rearrangements is usually a fusion between the immunoglobulin or T-cell receptor gene and a "caretaker gene" or proto-oncogene, such as *MYC*, resulting in deregulation of cellular proliferation.

The most frequent genetic abnormalities in childhood ALL are translocations that result in fusion of two genes that are important in the regulation of gene transcription in hematopoietic cells, such as *TEL*, *AMLI*, *MLL* or *AF4*. The fused genes produce a chimeric or fusion gene protein product that alters normal cellular function, frequently through regulation of signal transduction or transcriptional pathways [11,12].

It is important to note that the major genotypic forms of childhood ALL cannot be distinguished by morphology in most cases, and even by cytogenetics in some cases. An excellent example is the *TEL-AMLI* fusion that is generally cryptic in cytogenetic analysis and is important to identify by molecular analysis because of the excellent prognosis of these leukemias when treated with chemotherapy [13]. In contrast, rearrangements of the *MLL* gene in infants are associated with markedly inferior outcomes with chemotherapy [14]. Rapid identification of molecular abnormalities that can

Table 53.1 Cellular genotype defines major forms of childhood acute lymphoblastic leukemia

Molecular genetic abnormality	Translocation	Biochemical defect	Associated features	Recommended timing for HCT
B-cell lineage leukemia				
ETV6-RUNX1 fusion	t(12;21) cryptic	Transcription	Good prognosis with chemotherapy	Following relapse
BCR-ABL fusion	t(9;22)(q34;q11)	Signal transduction	Outcomes improving with TKIs + chemotherapy	Newer data now suggest transplant – likely following relapse
E2A-PBX fusion	t(1;19)(q23;p13)	Transcription	Pre-B phenotype, intermediate response to intensive chemotherapy	Following relapse
MLL-AF4 fusion	t(4;11)(q21;q23)	Transcription	Younger infants have poor prognosis	Controversial; early in very young – if using research protocol
MLL-ENL fusion	t(11;19)(q23;p13)	Transcription	Hyperleukocytosis	Following relapse
IGH-MYC fusion	t(8;14)(q24;q32)	Transcription	Extramedullary disease	Following relapse
IGκ-MYC fusion	t(2;8)(p12;q24)	Transcription	Extramedullary disease	Following relapse
IGλ-MYC fusion	t(8;22)(q24;q11)	Transcription	Extramedullary disease	Following relapse
Hyperdiploidy	None	Unknown	Good prognosis with chemotherapy	Following relapse
Hypodiploidy (<45 chromosomes)	None	Unknown	Poor prognosis with chemotherapy	Early in disease
T-cell lineage leukemia				
TAL1 (SCL) deletion	None	Transcription	Extramedullary disease, CD2$^+$, CD10$^-$	Following relapse
TCRδ-TAL1 (SCL) fusion	t(1;14)(p32;q11)	Transcription	Extramedullary disease, CD2$^+$, CD10$^-$	Following relapse
TCRβ-TAL1 (SCL) fusion	t(1;7)(p32;q35)	Transcription	Extramedullary disease, CD2$^+$, CD10$^-$	Following relapse
TCRα-MYC fusion	t(13;14)(q24;q11)	Transcription	Extramedullary disease	Following relapse
TCRδ-RBTN1 fusion	t(11;14)(p15;q11)	Transcription	Extramedullary disease	Following relapse
TCRδ-RBTN2 fusion	t(11;14)(p13;q11)	Transcription	Extramedullary disease	Following relapse
TCRδ-HOX11 fusion	t(10;14)(q24;q11)	Transcription	Extramedullary disease	Following relapse
TCRβ-LCK fusion	t(1;7)(p32;q35)	Signal transduction	Extramedullary disease	Following relapse

importantly affect the prognosis of ALL has allowed risk-adjusted therapy assignment to optimize outcomes. Despite advances in molecular diagnosis, cytogenetic studies, including fluorescence in situ hybridization (FISH), remain important for identifying leukemias with hyperdiploidy, confirming the results of molecular analyses, and guiding the development of molecular assays to detect specific rearrangements.

Biologic differences between pediatric and adult ALL

Chemotherapy outcomes in adults with ALL are notably inferior to results achieved in children. With intensive combination chemotherapy, more than 80% of children with ALL will be cured of their disease, whereas results in adult studies indicate survival rates of 40–50%, despite increasing adoption of similar treatment strategies [1–7,15,16]. Biological differences between adult and pediatric ALL likely influence response to chemotherapy and include age-dependent differences in immunophenotype, cytogenetic, and molecular genetic characteristics [17].

While the incidence of ALL increases in the elderly, there is also a marked peak in incidence in children between the ages of 2 and 5 years. The leukemias occurring within this peak are generally of B-precursor origin, express CD10 surface antigen, and are hyperdiploid, all features associated with an excellent response to therapy [18]. Interestingly, occurrence of this peak appears to be related to improvements in socio-economic status, as it did not occur in the early years of this century and does not currently occur in developing countries [19]. Worldwide, the lowest rates of childhood ALL are reported in black African children (4 per 10^6 annually), with rates approximately 10-fold higher in white Caucasian children [20–23]. These epidemiologic characteristics may indicate that this subset of childhood ALL has a unique etiology. Experimental studies indicate that at least two molecular events are required for leukemogenesis, and the age of the children in this peak suggests that the first of these events take place in utero [24,25]. The nature of the later events that trigger overt leukemia have been the subject of speculation centering around possible infectious etiologies, perhaps related to delayed exposure to common viruses leading to an abnormal immune response [19–21,26,27]. Genetic studies of stored blood samples collected at birth have confirmed the presence of an abnormal clone at that time in at least a proportion of children with ALL, some of whom develop overt leukemia as late as their teenage years [28,29].

The majority of both adult and childhood ALL cases (70–75% of adult and 85% of pediatric cases) are derived from B-lineage cells. Approximately two-thirds of childhood ALL cases express early pre-B-cell markers, in contrast to 50% of adult cases. This phenotype is associated with the best response to chemotherapy, regardless of patient age, perhaps because lymphocytes in this developmental stage are particularly susceptible to apoptosis, and so to killing by glucocorticoids and antimetabolites. Approximately 15% of pediatric and 25% of adult ALL cases express T-lineage markers [30–32]. Although some early studies indicated that T-lineage ALL was associated with poor outcome, treatment of these patients with intensive multidrug regimens has improved prognosis such that the T-cell phenotype in general is no longer an adverse risk factor in adults or children [33–35]. An exception to this is a newly recognized early T-cell precursor ALL (ETP-ALL), a distinct, previously unrecognized, pathobiologic entity that confers a dire prognosis with use of standard intensive chemotherapy. ETP-ALL is characterized by immunologic markers and a gene expression profile reminiscent of double-negative stage 1 thymocytes that retain the ability to differentiate into both T-cell and myeloid, but not B-cell, lineages. Whole genome sequencing shows that the mutational spectrum of this subtype shares characteristics of acute myeloid leukemia (AML) and the transcriptional profile of the blasts is similar to that of normal hematopoietic stem cells and granulocyte macrophage precursors, suggesting that this subtype of leukemia is a stem-cell disease [36,37].

Approximately one-third of childhood early pre-B leukemia cases are hyperdiploid (>50 chromosomes), in contrast to less than 5% of adults. Hyperdiploidy is associated with a particularly favorable response to chemotherapy, perhaps because of the ability to accumulate high levels of methotrexate polyglutamates [38–40]. The most frequent structural rearrangement in childhood ALL, present in 20–30% of cases, is the translocation t(12;21)(p13;q22), which encodes a chimeric fusion product of the *ETV6* and *RUNX1* genes [41–43]. In addition to the formation of the chimeric protein, the non-translocated *ETV6* allele is deleted in many cases. Loss of *ETV6* activity is clearly a secondary event in some cases, occurring in a subclone of leukemia. This observation suggests that loss of ETV6 expression gives an additional proliferative advantage to the malignant cells, possibly because the normal ETV6 gene product can interact with the ETV6-RUNX1 fusion protein in a dominant negative fashion [42]. The *ETV6-RUNX1* translocation seems to define a subgroup of childhood ALL characterized by age 1–10 years, a non-hyperdiploid karyotype, and an excellent prognosis [41]. The *ETV6-RUNX1* translocation occurs at a low frequency (<5%) in adult leukemia, which likely contributes to the poorer overall prognosis of adult ALL [44–47].

The Philadelphia chromosome t(9;22)(q34;q11) results in the production of a chimeric fusion protein derived from fusion of the *BCR* and *ABL* genes. In contrast to *ETV6-RUNX1*, the Philadelphia chromosome is frequent in adult leukemias (25–30%), infrequent in childhood leukemias (3–5%), and used to be associated with a reduced prognosis regardless of age [48,49]. Incorporation of tyrosine kinase inhibitors (TKIs) with chemotherapy has improved survival in the children with Philadelphia-positive ALL, and pending confirmation in follow-up studies, transplant is likely no longer routinely indicated for Philadelphia-positive ALL in first remission [50].

The biologic characteristics described here indicate that the majority of children with leukemia have disease likely to be responsive to current chemotherapy regimens with acceptable toxicity, for example, early pre- B disease with either hyperdiploidy or the cryptic ETV6-RUNX1 fusion transcript. In contrast, adult patients commonly have biologic features associated with drug-resistant disease, and less favorable immunophenotypes. The biologic differences between adult and pediatric ALL lead to important differences in the appropriate indications for transplantation for children with ALL compared with adults.

Outcome of sibling donor transplantation in children with ALL

Transplantation in first remission

Children with ALL with a limited number of very adverse biologic features, such as hypodiploidy, have sufficiently poor outcomes with chemotherapy that they may benefit from HCT in first remission. Results of HCT for childhood ALL in first complete remission (CR1) generally show a reduction in relapse rate with transplantation in CR1, and an increased treatment-related mortality (TRM) compared with chemotherapy. However, it is a continuing challenge for such analyses that study data no longer reflect contemporary outcomes with chemotherapy by the time they are sufficiently mature for publication. It is important to note that many of the criteria used to define high risk in each of these studies, for example. T-cell ALL and mediastinal mass, high white blood cell (WBC) count, and t(4;11), are no longer associated with markedly inferior outcomes with modern chemotherapy and would not currently be considered an indication for HCT in first remission.

Cooperative children's cancer therapy groups worldwide have successfully investigated the role of chemotherapy in the treatment of childhood ALL for over 30 years [1–7,51]. Considerable effort has been directed towards identifying subsets of children with inferior prognoses so that additional or alternative therapies can be targeted to these children, and the use of risk-adapted therapies has been one of the major achievements in the management of childhood ALL. Over time, approaches to risk classification have become more complex and more effective in predicting prognosis [52]. The simplest level of ALL risk classification is the use of National Cancer Institute (NCI)/Rome standard criteria (age and WBC count at diagnosis) to broadly categorize leukemias as high risk (WBC count ≥50,000/μL or age ≥10 years) or standard risk (WBC count <50,000/μL and age 1–9.99 years). These criteria are widely used to assign therapy for children with B-lineage ALL, but are less effective in categorization of children with T-lineage disease. The molecular genetics of the ALL blasts and the response of the disease to initial therapy (rapid or slow early response) are now routinely also used in risk classification, and intensified chemotherapy is given to children in poor prognostic groups [1]. In addition, the International Berlin–Frankfurt–Münster Study Group (I-BFM-SG) has pioneered the evaluation of minimal residual disease (MRD) by polymerase chain reaction in childhood ALL. MRD assessment at days 33 and 78 of treatment by two clonal Ig/TCR markers, with sensitivity of at least 10^{-4}, discriminates outcome within risk groups defined by traditional features. MRD-based stratification was found to be superior to that based on other clinically relevant risk factors, including age, blast count at diagnosis, and immunophenotype.

Typically, only a minority of children with ALL are considered for HCT in first remission. In an effort to identify children with very-high risk ALL who should be considered for HCT in first remission, Schultz et al. [52] proposed a new classification system and treatment algorithm based on a combined analysis of clinical, biologic, and early response data predictive of event-free survival (EFS) from previous ALL studies conducted by the Children's Cancer Group (CCG) and the Pediatric Oncology group (POG). A total of 11,779 children (aged 1–21.99 years) with newly diagnosed B-precursor ALL were consecutively enrolled by the CCG (December 1988 to August 1995, $n = 4986$) and POG (January 1986 to November 1999, $n = 6793$). A total of 6238 patients had informative cytogenetic data and were included in the retrospective analysis. The very high-risk group was defined in this analysis as those with extreme hypodiploidy (fewer than 44 chromosomes), t(9;22), and/or *BCR-ABL* fusion, and induction failure. These data are in agreement with reports from other cooperative study groups in the United States and Europe that reported significantly inferior outcomes in childhood ALL with t(9:22), with hypodiploidy and in infants [3,7].

At the time these data were published, outcomes reported with chemotherapy supported the use of HCT in CR1 in children with ALL falling into these categories, as outcomes with chemotherapy were clearly unsatisfactory. However, it is always important to continue to follow chemotherapy outcomes carefully over time, as newer drugs or other improvements in chemotherapy may improve survival sufficiently to allow the use of transplantation only in CR2, as TRM and late consequences of therapy are greater with transplantation than chemotherapy. This concept is best exemplified by the changing trends in transplantation for Philadelphia-positive ALL. The small number of Philadelphia-positive ALL cases has limited our ability to determine the effectiveness of early HCT in increasing survival. Pooled data from multiple clinical trials groups in general suggested an advantage for transplant in CR1 when a matched sibling donor was available, but not when alternative donor transplants were used. These data all preceded the availability of TKIs, however, which have had a major impact on the treatment of Philadelphia-positive ALL in children.

The TKI imatinib has been shown to have important activity in childhood ALL. Building upon work describing improved outcomes with use of imatinib together with intensive chemotherapy [53–58], a Children's Oncology Group (COG) study incorporated an escalating dose of imatinib with chemotherapy before maintenance therapy, whereas those with a matched sibling donor received a transplant. Continuous imatinib exposure improved survival in the children receiving the highest dose of imatinib, with a 3-year EFS of 80%, more than twice that of historical controls (35%). Importantly, outcomes in those receiving chemotherapy plus imatinib (88% 3-year EFS) were not statistically different from those see in children receiving imatinib and a matched sibling donor transplant (57% 3-year EFS), or an alternative donor transplant (71% EFS) (Figure 53.1). Imatinib appeared to improve survival by improving the outcome of children with a higher burden of MRD, and the highest risk group, the small number with induction failure. The follow-up of this study is not yet complete, but no relapses after completion of therapy have yet been reported. Although it remains possible that the addition of imatinib could have delayed but not prevented relapse, these data encourage the hope that the leukemia has been eradicated without the need for transplant, and that remissions will be sustained. Pending confirmation with longer follow-up, these data suggest that transplant is now not routinely needed for Philadelphia-positive ALL in CR1 [50]. In agreement with these findings, a small number of patients treated in Spain with a high-risk chemotherapy protocol (SHOP-2005) plus imatinib followed by transplant, showed improved outcome compared with historical controls [59].

Results of the European intergroup study of post-induction treatment of Philadelphia-positive ALL (EsPhALL), which is contemporary to the COG study, showed the safety and long-term efficacy of post-induction imatinib plus chemotherapy compared with the standard BFM backbone intensive treatment, using a risk-stratified approach for the treatment of patients on the basis of early response to therapy. The role of allogeneic stem-cell transplantation in first complete remission could not be addressed despite the large number of patients, since most patients in the study received a transplant [60]. Administration of imatinib has been explored in the post-transplant setting. Investigators have shown that imatinib is well tolerated when given prophylactically after transplantation, although current data are too limited to determine whether outcomes are improved [61]. Studies addressing these gaps and investigating the role of newer TKI inhibitors are in progress and will help define better the role of transplant in patients with Philadelphia-positive ALL.

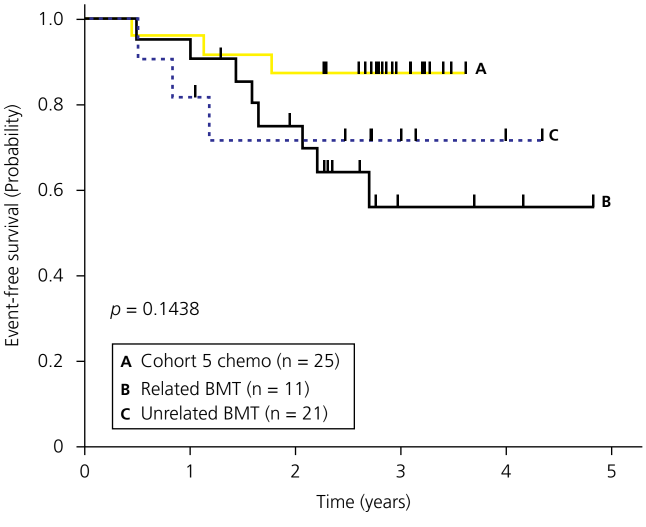

Figure 53.1 Comparison of event-free survival (EFS) for chemotherapy-only versus related donor HCT versus unrelated donor HCT in Philadelphia-positive ALL.

Children with severe hypodiploidy (<45 chromosomes) have poor outcomes with chemotherapy. In a report from the Children's Cancer Group (CCG), 6-year estimates of EFS for patients with 45 chromosomes, 33–44 chromosomes, or 24–28 chromosomes were 65, 40, and 25%, respectively (log rank, $p < 0.002$) [62]. In the largest study of hypodiploid ALL to date, Nachman et al. [63] reported on 139 patients with ALL and hypodiploidy (<45 chromosomes) collected from 10 different national ALL study groups and single institutions. In contrast to previous studies suggesting that near-haploid cases with 24–29 chromosomes have particularly poor outcome, this report found no difference in outcome between patients with 24–29, 33–39, or 40–43 chromosomes, with outcomes poor in all of these groups. However, compared with patients with fewer than 44 chromosomes, patients with 44 chromosomes had a significantly better EFS (52.2% vs. 30.1%, $p = 0.01$) and overall survival (OS) (69% vs. 37.5%, $p = 0.017$). Seventy-eight children with hypodiploid ALL transplanted in first or second remission with a matched sibling or unrelated donor (URD) between 1990 and 2010 have been reported to the Center for International Blood and Marrow Transplant Research (CIBMTR), and transplant outcomes are being analyzed. Based on an earlier analysis, 3-year survival was 65% [95% confidence interval (CI) 45–80%] in 29 patients undergoing matched sibling donor transplant, supporting the use of early HCT in this small subgroup (M. Eapen, personal communication).

Cooperative group studies have contributed the important observation that initial response of childhood ALL to therapy is a strong indicator of long-term outcome, with better outcomes in rapid early responders [64–66]. Additionally, it has been shown that a proportion of slow responders (whether measured by clearance of peripheral blasts after 7 days of prednisone or marrow examination after 7 or 14 days of induction chemotherapy) can be subsequently rescued by intensification of therapy [67,68]. Intensification of chemotherapy improves survival to around 70% in poor responders, so these children do not generally require transplantation in first remission. However, a small subset of slow responders fail to achieve remission after 28 days of chemotherapy, and for those children, if they do achieve remission, only 40% will survive, suggesting that early transplantation once remission is achieved might be of benefit [64].

The detection of MRD using immunophenotyping or molecular detection of residual cells is increasingly being applied to clinical trials of chemotherapy for ALL [69–72]. These studies have the potential to identify the small subset of children with primary induction failure and a poor prognosis based on residual MRD who may be candidates for transplantation in CR1. MRD measurements can also serve as a guide to the effectiveness of chemotherapy prior to transplantation in children in CR1 or beyond, as outcomes of transplantation are clearly improved in those with the lowest disease burden at the time of transplant [73,74]. MRD after transplantation is clearly undesirable and predicts relapse, and can be used as a trigger for interventions such as reduction or withdrawal of immune suppression, or infusion of donor lymphocyte infusion (DLI), although the efficacy of these strategies remains suboptimal.

Gene expression studies

Increased precision in risk assignment at diagnosis might be achieved in the future using array-based analyses. Current data are of great biologic interest, but interpretation is limited by the use of different and evolving platforms for analysis in different studies, and it is unclear whether these strategies augment MRD as a prognostic tool, rather than identifying the same subset of children with reduced prognosis using a different technology, although it may be hoped that in the future these studies will identify novel subsets with a poor prognosis [75–79].

A small number of studies have directly compared outcomes of children with very high-risk ALL transplanted in first remission with matched chemotherapy-treated controls. Some of these studies have shown superior outcomes in transplanted cases [80–82]. In a retrospective analysis of the ALL-BFM-90 and -95 trials, Schrauder et al. reported significantly improved 5-year disease-free survival (DFS) and OS with allogeneic HCT versus chemotherapy in pediatric patients with very high-risk T-cell ALL in CR1 [83]. Similarly, results from a prospective, collaborative group study reported a significant improvement in 5-year DFS, but not OS, for very high-risk pediatric patients with ALL in CR1 who had a donor versus those who did not [intent-to-treat (ITT) analysis], including those who had primary induction failure, and also those who underwent an MRD or URD allogeneic stem-cell transplant (SCT) versus those who received chemotherapy only (as treated analysis) [84]. In contrast, two consecutive MRC protocols identified cases considered to be very high risk for relapse (survival expected to be <40%), and offered sibling donor HCT to those with available donors [85]. The data showed a small benefit of 4.6% improvement in 10-year EFS in transplanted patients. However, when patients with a human leukocyte antigen (HLA)-matched donor were compared with those without, regardless of treatment received (ITT analysis), patients with a donor had an adjusted EFS 10.7% lower than those without a donor. Similarly, results of the Programa para el Tratamiento de Hemopatías Malignas (PETHEMA) ALL-93 trial [86] failed to show any advantage of HCT over chemotherapy in CR1.

These studies illustrate some of the challenges of transferring excellent single-center outcomes to cooperative group studies. Difficulties include heterogeneous populations, non-compliance with assigned therapy leading to selection bias, and transplantation at multiple smaller centers. Transplantation at centers with higher annual numbers of transplants and longer experience has been associated with improved outcomes [87,88]. Continuing investigation of the role of HCT in first remission will require careful attention to the optimization of statistical and clinical trial design, and the evaluation of newer transplantation strategies, including newer hematopoietic cell sources and perhaps reduced-intensity conditioning regimens.

Outcomes of transplantation in second or subsequent remission

Many single- and multiple-institution studies describe outcomes of HCT for patients with relapsed ALL, and often combine data for children and adults. In this chapter, where possible, the data from children are highlighted. Overall, results of sibling donor HCT for children with ALL in second or subsequent remission in single- and multi-institution studies have reported DFS ranging from 23% for patients with advanced disease to 35–64% for cases transplanted in second remission [89–94].

The length of first remission is key in determining the outcome of relapsed ALL in children. Survival rates are typically poor with chemotherapy when relapse has occurred early (commonly defined in US studies as duration of first remission less than 3 years) [95,96]. A proportion of children with later relapses can be long-term survivors after retreatment with chemotherapy [49,97–99]. The appropriate use of HCT or chemotherapy alone for children with relapsed ALL remains a controversial topic, and there have been no successful randomized studies to compare transplantation in second remission with further chemotherapy. A number of cooperative groups, including the COG, have attempted to compare outcomes of transplant and chemotherapy in randomized studies and have been unsuccessful, largely owing to lack of acceptance of randomization by either or both of physicians and parents.

In the absence of randomized data, the best available comparison comes from registry analyses. Eapen et al. compared 188 patients enrolled in POG chemotherapy trials and 186 children who received HLA-matched sibling transplants, treated between 1991 and 1997 (see above) [100]. For children with early first relapse (<36 months from diagnosis), risk of a second relapse was significantly lower after total body irradiation (TBI)-containing transplant regimens [relative risk (RR) 0.49, 95% CI 0.33–0.71%, $p < 0.001$] than after regimens based on chemotherapy alone. Patients receiving radiation-based regimens also had higher leukemia-free survival (LFS) and OS rates. In contrast, transplantation in CR2 did not offer advantage over chemotherapy for children with a late (36 months) relapse ($p = 0.78$). Transplant recipients who received a non-TBI-containing regimen fared poorly; recurrence rates were higher than those in children treated with chemotherapy alone, with correspondingly lower LFS and OS rates (Figure 53.2).

The Italian Bone Marrow Transplant group reported on 57 children who received allogeneic transplantation for ALL in second remission and compared them with 230 patients who received chemotherapy following their relapse [96]. They demonstrated that patients who had an early (<30 months) first relapse had significantly longer DFS following allogeneic transplantation than treatment with

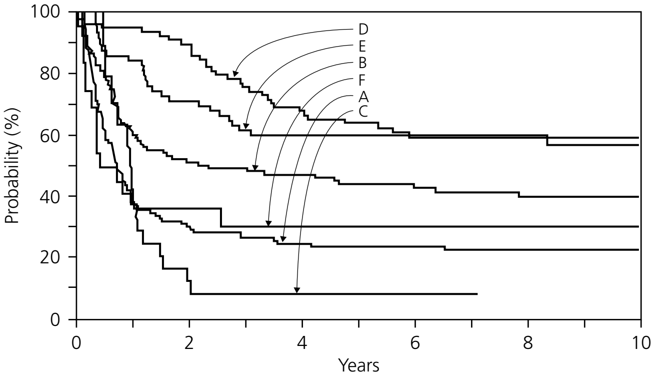

Figure 53.2 Probability of leukemia-free survival in CR2. A, Chemotherapy recipients after an early first relapse; B, transplant recipients with TBI regimens after an early first relapse; C, transplant recipients with non-TBI regimens after an early first relapse; D, chemotherapy recipients after late first relapse; E, transplant recipients with TBI regimens after late first relapse; and F, transplant recipients with non-TBI regimens after late first relapse.

chemotherapy. However, similarly to the IBMTR analysis, this advantage was lost in patients with a later relapse (in this study >30 months following diagnosis).

In a long term follow-up, a multicenter trial in Germany and Austria reported a significant improvement in 15-year EFS in pediatric patients with ALL who experienced a bone marrow (BM) relapse after treatment in the ALL-REZ BFM 87 trial and who subsequently underwent an MRD allogeneic HCT (n = 27) versus chemotherapy (n = 156) in CR2. The probability of EFS after allogeneic HCT was superior (0.59 ± 0.09) to that for the patients who received chemotherapy and radiotherapy as postremission treatment (0.30 ± 0.04, p = 0.026) [101].

Outcomes of 56 children with relapsed ALL were reported in a single-institution study in Australia [90]. All patients with a matched family donor (n = 20] received transplantation, and the other patients received chemotherapy (n = 32) or alternative donor transplants (n = 2). EFS at 8 years was 55% in children with an available family donor compared with 9.2% in patients without a matched family donor (p = 0.002).

In contrast, a US study reported no significant difference in 5-year DFS among pediatric patients with ALL in CR2 in the COG/CCG-1941 trial who underwent an MRD allogeneic HCT or were randomized to receive either an alternative (URD allogeneic or autologous) HCT or chemotherapy, although compliance with study recommendations was limited in this study [102]. Similarly, Harrison et al. found no significant difference in 8-year EFS in a MRC trial [103].

In a large multicenter population-based trial (ALL-REZ BFM 90), Tallen et al. reported that patients in high-risk groups did better with HCT than with chemotherapy (probability of EFS = 0.33 ± 0.05 vs. 0.20 ± 0.05, p < 0.005), suggesting that allogeneic HCT should be recommended in these high-risk patients achieving second complete remission. In this study, high-risk patients were defined as patients with very early BM relapse (<18 months from diagnosis) or any relapse of T-lineage ALL, early isolated BM relapse, or combined BM and extramedullary disease relapses (relapse >18 months from initial diagnosis and <6 months after cessation of frontline therapy) [104].

Taken together, these data indicate that generally HCT from a matched family donor is the best option for a child with an early marrow relapse of ALL or relapse of T-cell disease.

Some data suggest that similar benefit can be achieved with alternative donor HCT, especially a well-matched unrelated donor. Sarrinen-Pihkala et al. reported similar outcomes in children transplanted for ALL in CR2 using URD compared with MSD [105]. Similarly, advances in donor selection and transplantation using cord blood have led to similar outcomes to those obtained with geno-identical donors. This is discussed further under donor selection. Although survival may be equivalent, it is important to appreciate that risk of graft-versus-host disease (GVHD) is increased with the use of alternative donors, and is likely to have an impact on quality of life of survivors [106–108].

The majority of studies indicate that children with later relapse can achieve similar survival with chemotherapy to that with transplantation, so treatment options should be discussed carefully with the family.

Transplants performed beyond CR2 usually involve unrelated donors, as children with matched sibling donors are commonly transplanted in CR2. CIBMTR data on outcomes of 155 URD transplants, performed between 1990 and 2005 for children with ALL in CR3, showed 5-year LFS of 33% for the children with a second relapse 26 months beyond the first, and 26% for those with a second relapse less than 26 months after the first [107]. Although the outcomes are less than optimal, these data are perhaps better than might be expected, and indicate that in a proportion of children with multiply relapsed ALL, later retrieval is possible. Further analysis of predictors of survival in this group will be instructive in guiding future practice.

A careful reassessment of the morphologic, cytogenetic, and molecular genetic characteristics of the leukemia is essential at the time of relapse to confirm recurrence of the original disease and not development of a new secondary leukemia, either ALL or AML, perhaps related to the use of chemotherapy [109,110]. It is also important to rule out a second leukemia in a susceptible person, who has perhaps retained a premalignant population of cells, for example, with an ETV6-RUNX1 translocation, leaving them at risk for a new malignancy with similarities to the initial leukemia [111]. These children with a second primary leukemia, and not a relapse, can do well with further chemotherapy [112].

Reinduction chemotherapy is successful in achieving remission in 70–90% of children with relapsed ALL. The problem of how to manage a patient when attempts at chemotherapy reinduction fail has not been resolved. In some centers, such patients will be considered for allogeneic transplantation even in relapse. There are currently insufficient published data to predict outcomes accurately in these patients, although experience suggests extremely high TRM and a high post-transplant relapse rate because of resistant leukemic cells, limiting enthusiasm for such an approach.

When considering the role of HCT in children with ALL, it is important to recognize that there has been continuous improvement in chemotherapy outcomes, and that HCT can be associated with significant late morbidity [113]. Comparisons of HCT and chemotherapy outcomes must be contemporary and ongoing to allow appropriate therapeutic choices, and the impact of late complications such as GVHD on quality of life must be considered. Table 53.2 summarizes current general approaches to indications for HCT for children with ALL.

Selection of conditioning regimens

The conditioning regimen used to prepare a patient for an HCT for childhood ALL is expected to provide sufficient immunosuppression to facilitate donor cell engraftment, and cytotoxicity to assist in the eradication of residual leukemic cells. In the early years of transplantation, most regimens included TBI given in a single fraction. More recently, TBI has typically been administered in multiple fractions to reduce toxicity. Hyperfractionated TBI combined with CY, now considered a standard regimen, was first introduced for the treatment of children with leukemia by investigators at MSKCC [114]. After the original reports of the use of CY and TBI, several investigators added other chemotherapeutic agents to the regimen, or substituted other drugs for CY, in an attempt to improve outcomes. Although studies with some of these other combinations showed initial promise, additional toxicity often occurred and the long-term outcome was often not appreciably changed.

A large CIBMTR study compared 298 patients (adults and children) with ALL in CR1 or CR2 receiving HLA-matched sibling allografts after CY/TBI with 204 patients receiving etoposide/TBI [115]. Four groups were compared: CY/TBI <13 Gy (n = 217), CY/TBI of ≥13 Gy (n = 81), etoposide/TBI <13 Gy (n = 53), and etoposide/TBI of ≥13 Gy (n = 151). TRM did not differ by conditioning regimen, and in CR1 there were no significant differences in relapse,

Table 53.2 Indications for transplantation for childhood acute lymphoblastic leukemia

Stage of leukemia at time of BMT	Donor type	
	Matched sibling or one-antigen-mismatched family member	**Unrelated marrow or cord blood**
CR1, Philadelphia chromosome positive	Likely not indicated; improved results with TKIs + chemotherapy [50,59]	Likely not indicated; improved results with TKIs + chemotherapy [50,59]
CR1, t(4;11) or other MLL rearrangement in infant <1 year old at diagnosis	Transplant indicated in some but not all patients. Reported data suggest mixed results with HCT [167–169] – involve small numbers and careful prospective evaluation needed. Note: some infants have biologic characteristics of higher risk disease (infants with MLL translocations, aged <6 months at diagnosis and either a poor response to steroids at day 8 or a leukocyte count ≥300 g/L) may have improved outcome with HCT	Poor results with chemotherapy, mixed results for outcome with URD HCT [167–169]. Should be considered for patients with high-risk features. Data should be contributed to registries/group studies to allow evaluation of outcomes
CR1, >28 days to achieve CR	Transplant may be offered; limited data available comparing outcome with outcome of chemotherapy [52,84]	Transplant may be offered, particularly in cases with other high-risk features; data not available comparing outcome with outcome of chemotherapy
CR2, relapse with CR1 <36 months	Indicated. Outcome improved in transplant recipients in case–control comparison [96,100,101,104]	Indicated. Good outcomes reported in significant series of cases [105]; however, careful case-control comparison still needed to confirm improved outcome. Single and multicenter studies suggest outcomes can be equivalent to related donor BMT using URD matched at HLA -A, -B, -C, and -DRB1 [146,147]
CR2, relapse with CR1>36 months	Transplant typically not offered; chemotherapy offers an equivalent outcome [54,115–118]	Generally not offered to those with very late relapses, those with relapse just beyond 36 months may be considered. Single- and multicenter studies suggest outcomes can be equivalent to related donor BMT using URD matched at HLA-A, -B, -C, and -DRB1 [146,147]
CR3 and higher	Transplant indicated, cure with chemotherapy unlikely	Transplant indicated, cure with chemotherapy unlikely [107]
Relapse	Results poor; transplant not generally offered unless in context of investigation of new HCT strategies	Results poor; transplant not generally offered unless in context of investigation of new HCT strategies
Isolated extramedullary relapse	Registry data suggest no benefit from transplant [191]. Transplant not generally offered unless associated with marrow relapse	Transplant not generally offered unless associated with marrow relapse

LFS, or survival by conditioning regimen. In CR2, important differences in outcome among conditioning groups were identified. The risk of relapse, treatment failure, and mortality were lower in recipients of etoposide (regardless of TBI dose) or with TBI doses of ≥13 Gy in patients receiving CY. A striking reduction in relapse risk was observed in patients receiving ≥13 Gy TBI with CY compared with CY/TBI using <13 Gy of radiation ($p = 0.0016$). These data are further evidence of the contribution of the conditioning regimen to disease control in transplantation for ALL.

Concerns about the late effects of TBI in children have led to a number of studies of conditioning regimens using only chemotherapy. Early studies of busulfan (BU) and CY as a conditioning regimen focused on the treatment of myeloid malignancies, and data indicated that the regimen was adequate to achieve donor cell engraftment [116]. The use of a radiation-free conditioning regimen is an attractive option for young children if equivalent survival can be demonstrated as fewer late adverse effects on growth, endocrine, and cognitive function might be expected.

An IBMTR analysis of children with ALL receiving HLA-identical sibling donor HCT compared outcomes with conditioning regimes of CY and TBI ($n = 451$) or BU and CY ($n = 176$) [117]. The 3-year probability of LFS was significantly higher in the group receiving CY and TBI than in the group receiving BU and CY. The risk of relapse was similar in the two groups, but TRM was higher in children receiving BU and CY. Bunin et al. [118] reported similar inferior outcomes of a BU and CY conditioning regimen compared with TBI and CY in a small but prospective trial conducted by the Pediatric Blood and Marrow Transplant Consortium.

Together, these reports indicate that, in the past, modifications of conditioning regimens for children with ALL had limited success in improving outcomes. Inclusion of additional chemotherapeutic agents led, in some instances, to increased morbidity and mortality without significant improvement in long-term DFS. In addition, current data suggest reduced survival with radiation-free regimens.

A recent analysis of myeloablative TBI-containing conditioning regimens for pediatric ALL reported to the CIBMTR compared four commonly used regimens: (1) TBI 1000 or 1200 cGy + CY, (2) TBI 1000 or 1200 cGy + CY + etoposide, (3) TBI 1320–1400 cGy + CY, and (4) TBI 1320–1400 cGy + CY + etoposide [119]. This study included 765 patients with ALL aged <18 years at the time of HCT who received a graft from an HLA-matched sibling or an unrelated donor. Unrelated donor grafts included BM and UCB. All HCTs were performed between 1998 and 2007. All patients received myeloablative conditioning with a TBI-containing regimen (TBI >1000 cGy). The 5-year probability of relapse was similar in all four groups. However, TRM was higher (35% vs. 25%, $p < 0.02$) and overall survival lower (36% vs. 48%, $p < 0.03$) in group 4 (CY, higher dose TBI and etoposide) compared with group 3 (CY and higher dose TBI). Based on these findings, it was suggested that the addition of etoposide to a TBI ≥1320 cGy + CY conditioning regimen increases mortality risk and should be avoided in children and adolescents with ALL. In this study, the effect of conditioning regimen on transplantation-related and overall mortality was independent of patient age, donor source, and performance score.

These findings differ in some respects with the previous report from Marks et al. [115], which showed that TBI-containing regimens with etoposide alone were associated with superior leukemia control after transplantation. Patient age varied among studies; however, with the latest series limited to children and adolescents, the reported differences in risk may be related to differences in the biology of pediatric and adult ALL and/or differences in intensity of up-front chemotherapy regimens used to induce a second remission.

The inclusion of TBI in the preparative regimen is clearly associated with significant late effects, which are accentuated in pediatric populations, increasing reluctance to transplant very young children in particular, because of concerns regarding long-term growth and cognitive function [120–123].

Perkins et al. evaluated 13 children who were transplanted under the age of 3 years (range 0.58–2.93 years), with follow-up between 3 and 22 years, 11 of whom had received TBI [124]. All had IQs in the normal range. Phipps et al. performed a prospective study of neurocognitive outcomes of transplant [125]. A battery of neurocognitive measures were administered before admission and at 1, 3, and 5 years post-SCT. A total of 158 patients who survived were evaluated at 1 year after HCT. Subgroups of patients at relatively higher risk of poor outcomes were those undergoing URD transplantation, receiving TBI, and who experienced GVHD. Differences were seen in verbal IQ ($p < 0.01$), performance IQ ($p < 0.01$), reading ($p < 0.05$), and spelling ($p < 0.05$) and a marginal difference in math ($p = 0.06$) in recipients of TBI. The effects of TBI, although statistically significant, were small, reflecting a between-group difference of approximately three IQ points over a 5-year period, suggesting that these changes may not have been of great functional consequence [125]. These data suggest that TBI can be considered for young children with ALL, although careful follow-up and management of remediable late effects are essential.

The use of reduced-intensity transplant in ALL has lagged behind experience in AML, with enthusiasm limited by the mixed evidence for any benefit of allogenicity in disease control in ALL, and by concerns about disease progression in the period of establishment of donor hematopoiesis. Reduced-intensity transplantation is now being explored in adults with ALL, and is clearly feasible, although more detailed analyses of patients likely to benefit are ongoing [126–128]. Pediatric experience of reduced-intensity transplantation for ALL remains limited, as most children are able to tolerate myeloablative therapy. Verneris et al. described 38 reduced-intensity pediatric transplants for ALL reported to CIBMTR, with 30% EFS [129]. However, in registry studies it is difficult to ascertain the reason why reduced-intensity conditioning was used and what comorbidities might have been present, so further studies are needed to determine if this is a viable option for disease control.

Alternative donor HCT for children with ALL

Mismatched family member transplantations in children with ALL

Many or most of the problems of hematopoietic cell donor availability could be addressed using one-, two- or three-antigen-mismatched family member donors, who are available for almost every patient [130]. Early studies of highly mismatched related donor transplantations reported high rates of graft failure and GVHD, limiting enthusiasm for this approach [131,132]. Although newer transplantation approaches have shown improvement in outcomes, experience with transplantation using mismatched family member donors remains limited, and to a large extent focused in a small number of centers with particular interest and expertise in this strategy.

There are few data regarding the use of these transplants for uniform patient populations, although there are several series summarizing overall experience at single institutions. In reports of heterogeneous patient groups, a number of authors have shown that results using a one-antigen-mismatched family member as a donor can be comparable to those achieved using a matched sibling donor, while risk of treatment failure increases incrementally with increasing HLA disparity [133–135].

Investigators in Perugia, Italy, have pioneered the use of a high degree of T-cell depletion together with infusion of a high dose of haploidentical $CD34^+$ cells to overcome the problems of GVHD and graft failure associated with highly mismatched haploidentical grafts [136]. They demonstrated that donor-versus-recipient natural killer cell alloreactivity can eliminate leukemia relapse and graft rejection, and protect patients against GVHD in cases with AML. Unfortunately, activity against leukemia cells appeared to be specific for AML and not ALL blasts, and outcomes were not satisfactory in cases of ALL in this series.

A pediatric study using a similar approach described outcomes in 27 children with ALL (seven in CR1, ten in CR2, four in CR3, and six with refractory disease) [137]. Engraftment was rapid in 26 patients. Two patients who rejected the first graft and one patient with initial non-engraftment were successfully retransplanted. Survival for the group overall was 33%, and 44% for children in remission at the time of transplantation; none of the children transplanted without achieving remission survived. Relapse and infection were important causes of treatment failure.

Investigators in Bristol, United Kingdom, reported their experience of using haploidentical family members as donors for 34 children with leukemia, of whom 14 had ALL [151]. The conditioning regimen included CY and TBI (14.4 Gy in eight fractions). All patients received T-cell-depleted peripheral blood stem-cell grafts with a median CD34 cell dose of 13.8 (range 4.2–35.1) $\times 10^6$/kg, and 0.7×10^4 $CD3^+$ cells/kg. The actuarial survival at 2 years was 26% (95% CI 13–41%). Eight patients survived disease free with a median follow-up of 62 months.

A recent retrospective, multicenter, registry-based study analyzed the outcomes of children receiving a T-cell-depleted allograft from HLA-mismatched related donors, transplanted in European transplant centers, reported to the Pediatric Diseases and the Acute Leukemia Working Parties of the European Group for Blood and Marrow Transplantation (EBMT) registry [138]. A total of 127 children with ALL were transplanted from mismatched relatives from 1995 to 2004 in 36 EBMT centers. Twenty-two received a transplant in CR1, 48 in CR2, and 32 in CR3, and 25 were not in remission with 5-year DFS of 30% (±10%), 34% (±7%), 22% (±7%), and 0%, respectively. Acute GVHD was absent or grade I in 80 children, grade II in 13, grade III in six, and grade IV in three cases, and chronic GVHD was observed in 14 of the 84 patients at risk. The cumulative incidence of hematologic relapse at 5 years was 36% (±4%). The cumulative incidence of NRM at 5 years was 37% (±4%). In a multivariate analysis, only previous autograft was associated with increased NRM [hazard ratio (HR) 3.01, 95% CI 1.16–7.84, $p = 0.024$]. The estimated probability of OS at 5 years was 29% (±5%) for the whole cohort, 28% (±10%) for patients transplanted in CR1, 39% (±7%) for those in CR2, and 32% (±8%) for those in CR3.

Outcomes for children with ALL treated with haploidentical transplantation are perhaps disappointing when compared with well-matched unrelated donor marrow or cord blood grafts, but may represent the only treatment option for children with infrequent tissue types. New directions in the use of adoptive cellular immunity [139] and improved preemptive monitoring and treatment of viral infections appear to be promising in this respect.

Unrelated donor HCT

Donor selection

Historically, outcomes of URD transplantation have been inferior to those of sibling donor transplantation, and recommendations for transplant for ALL have differentiated between those with and without a matched sibling donor. The use of phenotypically matched URDs has increased in parallel with the remarkable growth of registries of HLA-typed potential BM donors, such as the National Marrow Donor Program (NMDP) in the United States, which facilitate the process of donor identification and marrow acquisition [140,141]. Additionally, refinements in HLA-typing technologies have allowed for more accurate matching at class I and class II loci [142,143]. Despite these improvements, donor identification can still be a logistic challenge, particularly for patients in whom remissions are likely to be short, such as those with ALL beyond first remission.

An improved search algorithm based on the conversion of HLA assignments of patients and donors into search determinants, and on allele and haplotype frequencies (Hap-Logic), is now routinely used by the NMDP registry, and greatly facilitates the identification of eight-allele-matched donors [144]. In a recent CIBMTR study of children with AML, ALL, chronic myelogenous leukemia (CML), and MDS undergoing allogeneic T-replete, myeloablative HCT between 1993 and 2006 included patients receiving BM from 1208 MSDs, 266 8/8 allelic-matched URDs and 151 0–1 HLA-mismatched related donors. Multivariate analysis showed that recipients of MSD transplants had less TRM, acute GVHD, and chronic GVHD, along with better DFS and OS, than the URD and mismatched related donor groups. Survival rate was lower with mismatched related donors compared with MSD (RR 1.55, 95% CI 1.21–1.98, $p < 0.001$). No statistical difference was found between URD and mismatched related donor transplantations in OS (RR 0.94, 95% CI 0.71–1.26, $p = 0.686$) [145].

Outcomes

Initial reports of the results of URD transplantations necessarily included small, heterogeneous groups of patients. As donor availability has improved, larger single-center experiences and registry studies are now being reported. Outcomes from different centers show some variability, which may reflect heterogeneous patient populations or differing treatment strategies and provision of supportive care. Taken together, DFS for children transplanted in first and second remission is generally in the range 40–50%, and outcomes are not markedly different from those reported for related donor HCT.

A CIBMTR report compared long-term survival after unrelated and sibling donor HCT for acute leukemia (ALL and AML) in children younger than 18 months [146]. Although leukemia recurrence was lowest after URD HCT in first clinical remission, the OS and LFS rates were similar after matched sibling and URD HCT, after adjustment for disease status. Relapse, OS, and LFS did not differ by graft type (BM versus UCB) or type of leukemia. This was confirmed in the recent update of experience in Bristol, United Kingdom; 2-year OS was identical for matched sibling and well-matched URD transplants (Figure 53.3) [147].

Taken together, these data indicate that in children, good outcomes can be achieved with URD HCT. Improvements in HLA typing have facilitated optimum donor selection, and currently a URD molecularly matched at HLA-A, -B, -C, and -DRB1 is considered ideal and likely equivalent to a genotypically matched sibling donor.

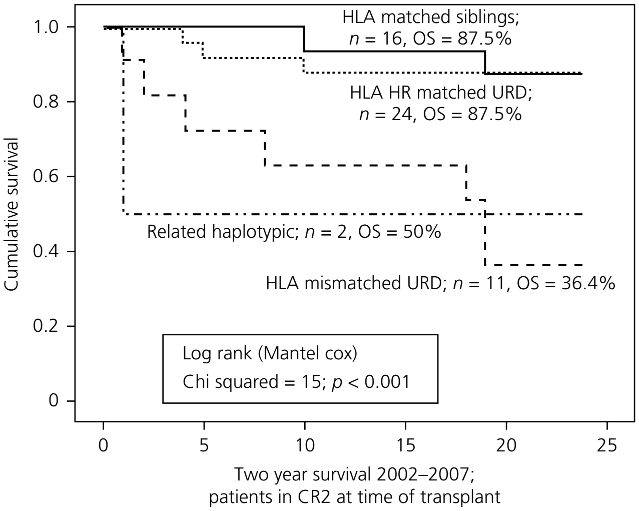

Figure 53.3 Two-year overall survival of patients in CR2 at time of transplant (2002–2007). HLA-matched sibling and URD transplants had identical OS at 87.5%.

As larger series of URD HCTs are being reported, it is now possible to evaluate prognostic factors influencing the outcome of URD HCT for children with ALL, although there is some variation between studies, perhaps due to variability in sample size and the population studied [148].

The impact of acute GVHD on relapse risk in ALL remains a controversial topic, as evidence for an important graft-versus-leukemia (GVL) effect has been at best mixed over the years, with generally poor responses to donor lymphocyte infusions [149]. Recent analysis of a large pediatric URD cohort showed decreased risk of relapse in children who developed acute GVHD, supporting the belief that there may be a benefit of GVHD in disease control [150].

The possible role of killer immunoglobulin-like receptor (KIR) mismatch in control of ALL has also been controversial. Early studies showed some benefit of KIR mismatch as imputed from HLA typing in AML, but not in ALL [136]. Additional studies using more direct measurement of KIR genotype and phenotype (a receptor–ligand model) support an important biologic effect in vitro and in vivo [151,152].

In contrast, other clinical studies have shown no impact of KIR mismatch, perhaps due to variability in the methodology used to determine KIR incompatibility, and in transplant technique, particularly the degree of T-cell depletion. Currently, there is insufficient evidence to recommend the selection of KIR-mismatched donors in children with ALL.

The increased mismatch associated with URDs might be hoped to bring with it more GVL effect and hence less relapse than sibling donors. Unfortunately, a CIBMTR analysis did not support this hypothesis for adults with ALL, AML, or CML [153].

The effectiveness of the GVL effect after cord blood transplant has been a concern in light of the generally reduced incidence of GVHD. However clinical studies have not demonstrated increased relapse associated with use of cord blood compared with sibling or URD transplants [154,155]. These data indicate that URD transplantation offers a cure for some children with ALL who are unlikely to be cured with chemotherapy. Challenges that remain, all of which are shared with sibling donor transplantation to a greater or lesser extent, include a high rate of GVHD (particularly with unmanipulated grafts), early and late infections (particularly in T-cell-depleted grafts), and the continuing problem of relapse. More intensive initial chemotherapy regimens may yield a population of children with highly drug-resistant relapsed disease, requiring novel approaches for cure.

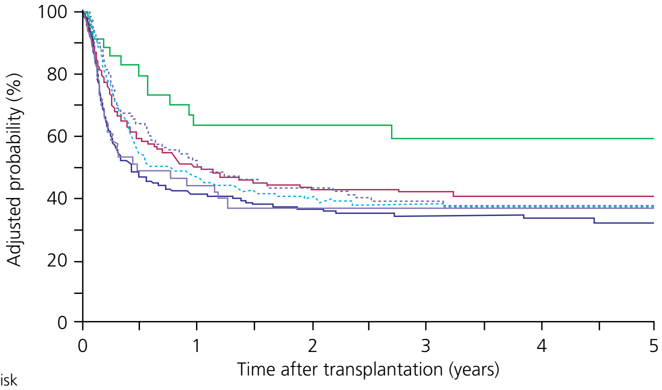
UCB transplantation for children with ALL

The establishment of banks of cryopreserved UCB for use in transplantation has been an important development in the treatment of children with ALL [156,157]. Potential advantages of UCB include immediate availability of stored units for transplantation once identified (particularly valuable for patients in whom remissions are likely to be short) and reduced GVHD, a major reason for treatment failure in recipients of URD marrow. In the last two decades, with the improvement in our understanding of factors implicated in expanding the availability of not just URD, but especially unrelated cord blood unit, has significantly shortened the search time to identify a compatible unrelated marrow donor or cord blood [158]. This is particularly advantageous in children with ALL, in whom achievement of remission can be difficult, and the ability to move to transplantation as soon as remission is achieved can be valuable. Initial reports of outcomes of UCB transplant procedures have been limited to relatively small series, although larger single-center experiences and registry series are now being reported.

As experience with UCB transplantations has increased, it has become possible to compare outcomes of UCB transplants with those of other graft sources to assist physicians in donor selection. A registry comparison of URD marrow (T-cell-depleted and T-cell-replete cases analyzed separately) and UCB transplantations in children with leukemia indicated equivalent survival among the three categories. Acute GVHD was reduced in UCB recipients compared with recipients of T-cell-replete marrow, and more relapses occurred in the T-cell-depleted marrow group than in the cord blood grafts [159,160]. In an important study that has influenced clinical practice, Eapen et al. [161] compared 503 children with acute leukemia transplanted with UCB with 282 BM recipients between 1995 and 2003. A total of 495 patients with ALL were included, 186 in the BM group and 309 in the UCB group. Clinical data were obtained from the CIBMTR and the National Cord Blood Program of the New York Blood Center. In comparison with allele-matched BM transplantations, 5-year LFS was similar after transplantation of UCB mismatched for either one or two antigens, and possibly higher (numbers were very small) after transplants of HLA-matched UCB (Figure 53.4). TRM rates were higher after transplantation of two-antigen HLA-mismatched UCB (RR 2.31, $p = 0.0003$) and possibly after one-antigen HLA-mismatched low cell dose ($<0.3 \times 10^5$/kg) UCB transplants (RR 1.88, $p = 0.0455$). Relapse rates were lower after two-antigen HLA-mismatched UCB transplants (54%, $p = 0.0045$). These data support the use of one- or two-antigen HLA-mismatched UCB with units of adequate size in children with acute leukemia who need transplantation.

A report from the IBMTR and National Cord Blood Program [161], including a large number of patients, showed similar GVHD rates and a lower relapse rate in patients receiving two-antigen HLA-mismatched UCB transplantation compared with matched BM transplantations, possibly indicating a greater, or at least equivalent, GVL effect. Adding another layer of complexity, a preliminary study comparing single unit cord blood transplant with double cord blood transplant suggested reduced relapse with the use of double cord blood transplants[162]. The mechanism of such an effect is unclear, although the incidence of acute GVHD was higher in recipients of double cord blood transplants, and these two observations may be related. This initial study included mostly adults in the double unit group and mostly children in the single unit group, as assignment was based on available cell dose, complicating interpretation of the data.

To explore this question further, a recent prospective pediatric study compared overall survival for recipients of a single UCB unit treated for hematologic malignancy on the original Cord Blood Transplantation (COBLT) Study ($n = 191$) conducted from 1999 to 2004 with the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) 0501 study ($n = 113$) conducted from 2006 to 2012. All patients received TBI 1350 cGy and cyclophosphamide 120 mg/kg. Patients enrolled in COBLT also received equine ATG 90 mg/kg and those on BMT CTN 0501 fludarabine 75 mg/m^2 with GVHD prophylaxis consisting of cyclosporine/methylprednisone and cyclosporine/mycophenolate mofetil, respectively. The 1-year



Numbers at risk		0	1	2	3	4	5
HLA-matched cord blood	—	35	20	17	13	11	8
HLA-matched bone marrow	·····	116	62	45	35	29	24
One-mismatched cord blood (high cell dose)	—	157	72	55	44	32	25
HLA-mismatched bone marrow	·····	166	77	60	53	44	30
One-mismatched cord blood (low cell dose)	—	44	19	13	12	10	6
Two-mismatched cord blood	—	267	100	67	49	34	21

Figure 53.4 Probability of leukemia-free survival after BM and UCB transplantation adjusted for disease status at transplantation. (For a color version of this figure, please see the color plate section.)

probabilities of overall survival were 57% (95% CI 50–64%) in COBLT and 71% (95% CI 62–79%) in BMT CTN 0501 ($p = 0.01$). Although it is not possible to prove which factor(s) played the greatest role, it is the "package" including conditioning and GVHD prophylactic regimens, supportive care, method of unit selection, and transplantation period combined that contributed to the improved survival observed in recipients of a single UCB unit [163].

Autologous transplantation for children with ALL

Autologous transplantation has generally proved disappointing in childhood ALL and is currently infrequently performed. Early, relatively small studies, generally from single centers, described fairly encouraging results [164,165]. However, these studies commonly included children with both early and late relapses, and those with isolated extramedullary relapses, some of whom would be expected to have a good outcome without transplantation of any kind, making interpretation of the data difficult.

Purging of the autograft of contaminating leukemia cells is an attractive concept, and has been attempted by a number of investigators. Overall, the outcomes of these transplantations were disappointing, and there were no clear data that outcomes were superior to those which could be achieved with chemotherapy alone or with unpurged grafts.

Increasing availability of URD marrow and cord blood has significantly reduced the number of children with no available allogeneic stem-cell source. In addition, continuing improvements in outcomes of allogeneic transplantations in children, particularly using URD stem-cell sources, with TRM of <15% now achievable, leaves little place for autologous transplantation in children with ALL.

Special pediatric considerations

Transplantation of infants with ALL

Treatment of infant ALL presents particular challenges because of variability in outcomes between the various genetic subtypes. Some children with infant ALL have a reasonable prognosis with chemotherapy (those with biologic characteristics similar to those of older children), whereas others (with very young age, high WBC count at diagnosis, and the *MLL* rearrangement) have possibly the most disappointing outcomes in childhood leukemia [14]. In addition, late adverse effects of treatment are a particular concern for this vulnerable group of small children. As a result, transplantation decisions are especially critical in infants.

Molecular rearrangements that involve the *MLL* gene occur in a high proportion of leukemias arising in infants less than 1 year of age (Table 53.1). Fusion between the *MLL* gene and the *AF4* gene as a consequence of a t(4;11)(q21;q23) translocation is the most frequent rearrangement. *MLL* gene-rearranged infant leukemias frequently have marked leukocytosis and a mixed-lineage phenotype (expressing both early B-cell and monocyte markers) [166].

Because of the poor response to chemotherapy, infants with *MLL*-rearranged ALL are often considered as candidates for early transplantation. Unfortunately, there are no prospective series of HCTs for infants, and outcomes are difficult to compare with those achieved with chemotherapy because of lack of uniform criteria for transplantation eligibility, varying donor sources, and the relatively small numbers of patients transplanted.

In the CIBMTR study discussed above, Eapen et al. [146] showed comparable long-term survival after sibling, URD, and UCB transplantation for acute leukemia (49% ALL and 51% AML) in children younger than 18 months. These data suggest that if transplantation is indicated, related and unrelated donors can be considered to be equivalent, but they do not address the issue of the relative roles of HCT and chemotherapy in CR1.

Establishing without doubt that HCT can improve outcome compared with chemotherapy in high-risk infants in CR1 requires a randomized study, and such a trial remains challenging owing to the rarity of this disease and to the logistic challenges of performing such studies, as discussed earlier. Recently, Dreyer et al. reported on data from infant ALL trials of the Children's Cancer Group (CCG 1953) and Pediatric Oncology Group (POG 9407) that used a similar chemotherapy backbone and advised allogeneic HSCT to be performed in *MLL*$^{+}$ cases. The 5-year EFS rates were 50.9% in the transplantation group and 48.7% in the chemotherapy-only group, suggesting no clinical benefit for HSCT in CR1 for infants with *MLL*$^{+}$ ALL [167].

The larger international Interfant-99 study enrolled 482 infants with ALL from 22 countries between 1999 and 2005. Eligible patients were risk stratified according to their peripheral blood response to a 7-day prednisone prophase, and then given a hybrid regimen based on the standard protocol for ALL, with some elements designed for treatment of AML (containing intensified cytarabine). In an ITT analysis, EFS and OS at 4 years were 46.0% and 55%, respectively. Factors prognostic of poor outcome included *MLL* gene rearrangements, very high WBC count ($>300 \times 10^{9}$/L), age younger than 6 months, and a poor response to the prednisone prophase. The 4-year DFS did not differ significantly in high-risk patients treated with chemotherapy alone (37.4%) versus chemotherapy plus HCT (50.2%) when adjusted for time to transplantation ($p = 0.19$). However, in a subset analysis, HCT in CR1 was associated with a significantly better DFS in infants with *MLL* translocations, aged <6 months at diagnosis and either a poor response to steroids at day 8 or a leukocyte count ≥300 g/L. In this subset of infants, HCT in CR1 was associated with a 64% reduction in the risk of failure resulting from relapse or death compared with chemotherapy alone, suggesting that this subgroup of high-risk infants may benefit from HCT [168,169].

While data from these multicenter reports are perhaps the best available, interpretation is limited by the small number of patients transplanted, multiple donor types, absence of standardized eligibility requirements, and absence of standardized treatments. There is a clear need for further prospective studies to define the role of HCT in infants with genetically defined leukemias that are at high risk for treatment failure. Such studies will need to be multi-institutional and possibly multinational (as was Interfant-99), as infant leukemia is rare. Studies should include evaluation of the late consequences of therapy in survivors, as morbidity can be significant in young children.

Transplantation of children with Down syndrome and ALL

Children with Down syndrome have an approximately 20-fold increased risk of leukemia, and historically reported to have increased treatment related toxicities, potentially related to increased cellular sensitivity to chemotherapeutic agents. However, some studies have shown chemotherapy outcomes as good as those seen in children with ALL without Down syndrome [170]. A review of the CCG experience, the largest analysis to date of this population, demonstrated decreased EFS and OS in children with Down syndrome and ALL enrolled in CCG trials when compared with children with ALL without Down syndrome [171]. Subset analysis revealed that poorer outcomes were restricted to the NCI standard-risk children (OS 70% vs. 85%, $p = 0.001$; EFS 56% vs. 74%, $p = 0.001$). The NCI high-risk subset of ALL and Down syndrome patients receiving more intensive therapy fared as well as their non-Down syndrome counterparts (OS 63% vs. 66%, $p = 0.7$; EFS 62% vs. 59%, $p = 0.9$), suggesting that, with modern supportive care, children with Down syndrome can tolerate intensive therapy.

Rubin et al. [172] reported 27 patients with Down syndrome (18 collected from a survey of BM transplantation centers and nine from the literature). Sixteen received a graft from an HLA-matched sibling, two from non-sibling family members, and four from URDs, and five received autologous grafts. This study included 14 children with ALL, nine in second remission and five in third remission. Five of the 14 ALL patients were surviving 9–60 months post-transplantation. The authors identified a high rate of regimen-related toxicity in these patients (39% cumulative risk of death in remission at 3 years). A high frequency of lung problems and airway problems, including upper airway obstruction due to severe mucositis, was common, perhaps associated with the use of methotrexate. Despite the significant toxicity, relapse-free survival for the whole group was 44% at 3 years, comparable to results seen in children with ALL without Down syndrome.

A retrospective case series of 11 children with Down syndrome who underwent HCT showed improvement in TRM, with a day 100 mortality of 18% [173]. Relapse was the most frequent cause of post-transplant mortality, with a 45% incidence of death due to recurrent disease. The decrease in TRM was possibly attributable to improved supportive care, advances in HLA typing, and relatively increased experience with HCT in children with Down syndrome.

Role of second transplant procedures for relapse

The most important cause of treatment failure following transplantation for childhood ALL is recurrent leukemia. Additional chemotherapy can induce further remission in a proportion of patients, although very few will survive long term. Experience with the use of second transplants following relapse after BM transplantation is limited. The CIBMTR reported on 114 recipients of HLA-identical sibling grafts who received a second allogeneic HCT for treatment of relapse between 1978 and 1989 [174]. Twenty-nine of these patients had ALL. LFS for all the ALL cases was 21% (95% CI 14–30%); however, outcomes were extremely poor in patients who had relapsed less than 6 months after their first transplant, in whom LFS was only 7% (95% CI 2–19%), largely as a consequence of high TRM. Patients with long remissions after their first transplant, those with good performance status, and those achieving remission after their initial post-transplant relapse had the best outcomes. Series of second transplantation procedures, each including a small number of ALL cases, also reported high early TRM and poor long-term survival [175–177]. A common theme of these reports is the importance of length of remission after transplant, with poor survival after a second HCT in those experiencing early relapse [178]. Although these procedures remain challenging, in the current era, both the careful assessment and eradication of MRD prior to second HCT can lead to better patient selection, and improved outcome in those with a long remission after the first HCT.

Conclusion

The treatment of childhood ALL with chemotherapy has been a story of remarkable success, with survival rates in excess of 80% in the majority of studies. This success is counterbalanced by the fact that current chemotherapy is still inadequate for the almost 20% of cases who will relapse. As ALL is the most frequent malignancy in children, relapsed ALL remains one of the most frequent causes of death from malignant disease in childhood. Determining the appropriate role for HCT in childhood ALL has been a dynamic process, as success with chemotherapy has increased and additional hematopoietic cell sources have become available.

Serial, large-scale, essentially population-based randomized studies have led to the improvements in outcomes of chemotherapy for ALL. Application of a similar rigorous approach to evaluation of the role of HCT has not proved possible, and significant uncertainty remains in some areas. Access to HCT has been enhanced by improvements in the availability and selection of unrelated hematopoietic cell donors and the development of URD UCB as a hematopoietic cell source. Indeed, outcomes with URD HCT have improved such that results are now equivalent to those for sibling donor HCT in well-matched cases.

Future improvements in outcome and applicability of HCT for childhood ALL may result from the development of methodologies to identify at the earliest possible time children who are destined to relapse, allowing HCT in first remission when outcomes are superior. The detection of MRD in children receiving chemotherapy, either as a harbinger of relapse or as a measure of inadequate early response to therapy, will allow early referral for HCT as intensification therapy [70,72,179–181]. It is important to know that the significance of MRD varies in different genetic subtypes of leukemia. For example, MRD is cleared more promptly in children with ALL and ETV6-RUNX1 compared with children with favorable trisomies, both groups having an excellent long term prognosis [182]. Some studies have also shown association between gene expression profiling of ALL blasts at diagnosis and distinct immunophenotypic and genetic subtypes of ALL, treatment outcomes, and risk of relapse [78,183–185]. Further validation of these and similar findings in the future could allow early referral of children with ALL destined to relapse for HCT in first remission.

In recent years, similarly there has been growing interest in the role of MRD as a predictive marker for relapse following allogeneic transplantation. Most studies have shown that MRD detection in pre- and/or post-HCT samples predicts increased risk of relapse following HCT [69,71,74,186,187].

Different approaches have been suggested to help improve transplantation outcomes using MRD detection to modify either pre- or post-transplant therapy, for example, additional cytoreductive therapy pre-transplant to reduce the malignant clone and render the patients MRD negative, designing transplant protocols favoring the development of GVHD to increase the GVL effect, the use of donor lymphocyte infusion, etc.

Some of these interventions are limited by the practicality of these approaches. For example, heavily pretreated patients have limited options for further chemotherapy prior to transplantation, and rapid withdrawal of immunosuppression and donor lymphocyte infusions is associated with the risk of life-threatening GVHD and has very limited efficacy.

Therefore, although it is possible to identify patients at risk of relapse with MRD detection, strategies to respond to that information are limited. Also, many questions remain unanswered; for example, should MRD-negative status be used to assign patients to non-transplant treatment options to prevent TRM and long-term toxicity? Efforts to assess the clinical significance of pretransplant MRD in children with ALL are hampered by the lack of prospective studies in large cohorts of homogeneously treated patients.

Improved strategies for donor selection using molecular methods of HLA typing, or examination of non-HLA loci that influence HCT, also have potential to improve outcomes [188,189]. Inclusion of chemotherapy agents such as etoposide or thioTEPA (*N*-triethylenethiophosphoramide) in the conditioning regimen may reduce relapse and improve survival. Lastly, targeting of conditioning therapy with radioimmunoconjugates offers the possibility of reducing radiation toxicity while maintaining the therapeutic effect [190].

CHAPTER 54

Hematopoietic Cell Transplantation for Myelodysplastic Syndromes and Myeloproliferative Neoplasms

H. Joachim Deeg
Fred Hutchinson Cancer Research Center, University of Washington, Seattle, WA, USA

Introduction

Myelodysplastic syndromes (MDSs) and myeloproliferative neoplasms (MPNs) represent two broad categories of chronic myeloid malignancies. Both are clonal diseases of hematopoietic precursors/stem cells. In contrast to acute leukemias, the course of MDS and MPN may extend over years or even decades. However, both disorders have the potential of evolving to acute leukemia, typically with myeloid characteristics. Alternatively, patients will have progressive blood cytopenias and hematopoietic failure. Chronic myelomonocytic leukemia (CMML) may have more dysplastic or more proliferative features and, in the World Health Organization (WHO) classification, has been placed in the category "Myelodysplastic/myeloproliferative neoplasms" [1]. Whether these diseases evolve towards acute leukemia or severe cytopenias, both paths eventually prove fatal. Chronic myeloid disorders can occur at any age, but the incidence increases progressively with age.

General considerations for hematopoietic cell transplantation in patients with MDS and MPN

Hematopoietic cell transplantation (HCT) has proven curative potential for patients with MDS and MPN, but the indications for and the optimal timing of HCT are controversial. The frequently indolent course often renders physician and patients reluctant to accept the potential risks associated with HCT. Although the day 100 mortality has declined to less than 10% or even 5%, non-relapse mortality (NRM) overall has been in the range 20–25%, causes including organ toxicity, graft-versus-host disease (GVHD), and infectious complications. Particularly in older patients, with reduced biologic reserve and tolerance to certain therapies, those issues are most relevant. Comorbid conditions in older patients contribute to the problem. Sorror et al. developed an HCT-specific comorbidity index (HCT-CI), which provides useful guidance for risk assessment before HCT [2]. Another risk classification, proposed by Parimon et al. [3], heavily based on pulmonary function, also considers the donor type in the risk assessment.

A Markov decision analysis by Cutler et al. [4] showed that in patients with MDS the International Prognostic Scoring System (IPSS) was useful in determining the timing of HCT in patients with human leukocyte antigen (HLA)-identical sibling donors and were transplanted after receiving high-intensity ("myeloablative") conditioning regimens: the higher the IPSS risk score, the more likely patients were to extend their life expectancy by HCT. A more recent analysis in older individuals transplanted after reduced-intensity conditioning (RIC) reached similar conclusions: patients with low-risk MDS (IPSS low or intermediate-1) are unlikely to benefit from HCT (quality or prolongation of life). Patients with higher risk disease stand to benefit from HCT, although a significant gain was apparent only after several years of follow-up [5]. Cytofluorimetric analyses of marrow cells indicated that IPSS intermediate-1 and low-risk patients can be further subdivided, at least with regard to relapse risk, on the basis of phenotypic aberrancy of marrow cells [6]. A subcategorization of patients with "low-risk disease" in the revised IPSS (IPSS-R), distinguishes patients with <5% myeloblasts in the marrow and those with >2% and <5% [7] (Table 54.1). For patients with MPN, a decision analysis for HCT is currently under way; two recent studies did find a highly significant correlation of HCT outcome with DIPSS (Dynamic IPSS; see below) [8,9].

Granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood progenitor cells (PBPCs) are currently the most widely used source of stem cells and are associated with decreased rates of graft rejection and relapse in patients with MDS or MPN (compared with marrow cells). However, the results of a randomized trial comparing marrow with PBPCs from unrelated donors in patients with various diagnoses showed a higher incidence of chronic GVHD with PBPCs [10]. There was no significant difference in the relapse rates between the two arms, but lower relapse rates with PBPCs have been observed in other studies [11]. Nevertheless, chronic GVHD may severely reduce the quality of life, and the use of PBPCs over marrow is being reassessed. Umbilical cord blood is an alternative stem-cell source, and successful HCT has been reported in patients with MDS [12]. Advantages of umbilical cord blood include the rapid availability and greater tolerance for HLA disparity, allowing for the use of mismatched units, thereby increasing the donor pool. However, cell numbers in cord blood units (along with the degree of HLA mismatching) are important determinants of engraftment. The strategy of infusing two units of cord blood has resulted in accelerated engraftment; more studies are needed to examine this modality in patients with MDS [13]. There is little experience with cord blood in patients with MPN.

The selection of donors on the basis of histocompatibility [14] is discussed in Chapters 44 and 45. Patients with MDS or MPN have

Table 54.1 IPSS-R prognostic scores

Variable	**Score**						
	0	**0.5**	**1**	**1.5**	**2**	**3**	**4**
Cytogenetics[a]	Very good		Good		Intermediate	Poor	Very poor
Marrow Blasts (%)	≤2		>2–<5		5–10	>10	
Hemoglobin (g/dL)	≥10		8–<10	<8			
Platelets (× 10^9/L)	≥100	50–<100	<50				
Neutrophils (× 10^9/L)	≥0.8	<0.8					

IPSS-R scores and expected survival (years)

Patient age (years)	**Risk category (score)**				
	Very low (≤1.5)	**Low (>1.5–3)**	**Intermediate (>3–4.5)**	**High (>4.5–6)**	**Very high (>6)**
Any	8.8	5.3	3.0	1.6	0.8
≤60	NR	8.8	5.2	2.1	0.9
>60	7.5	4.7	2.6	1.5	0.7

[a] Categorized according to Schanz et al. [29].

shown virtually identical results with HLA-identical siblings and with unrelated donors selected by high-resolution HLA typing (DNA sequencing). Promising results are also being obtained with transplants from HLA-haploidentical related donors.

As with other indications, GVHD has remained the most frequent complication after allogeneic HCT for MDS and MPN. Approximately 40–50% of patients transplanted from HLA-identical siblings and 50–60% transplanted from unrelated donors will develop acute GVHD requiring therapy. Chronic GVHD occurs in 30–70% of patients. Calcineurin inhibitors combined with methotrexate, mycophenolate mofetil, or sirolimus are widely used for prophylaxis. Glucocorticoids remain front-line therapy for treatment of established GVHD (see Chapters 83 and 84).

High-dose conditioning regimens are offered to patients up to 65 or 60 years of age, with HLA-identical siblings or unrelated donors, respectively [15]. RIC regimens allow the acceptable upper age for HCT to be expanded; even patients in their 70s have been transplanted successfully [16]. This is an important development as patients with MDS or MPN tend to be in their 60s or even 70s. However, although treatment-related mortality (TRM) is lower with RIC, the relapse incidence tends to be higher than with high-dose regimens, an important consideration since patients with MDS (or MPN) have generally not been treated aggressively with cytotoxic therapy before HCT [9]. Patients with the lowest disease burden tend to enjoy the highest success rates, raising the issue of pre-transplant debulking chemotherapy [17,18]. Generally, patients who have elevated myeloblast counts (≥5% in the marrow) receive therapy with demethylating agents or with induction-type chemotherapy before HCT with RIC. The approach has been less consistent in patients who are prepared for HCT with high-intensity regimens. A beneficial effect of debulking in overcoming disease-associated risk factors, such as adverse cytogenetics, is doubtful.

A French study showed that patients with secondary/treatment-related MDS who achieved remissions after chemotherapy had higher relapse-free survival (RFS) after HCT than patients who did not respond [19]. Similar observations were reported by others [20,21]. However, patients who did not achieve remissions had lower RFS than patients who had not received chemotherapy, suggesting that pre-HCT therapy selected for "treatment-responsive" patients.

Data on the role of debulking chemotherapy in MPN are sparse. However, one report describing a cohort of 14 patients with transformation of MPN to leukemia suggested that patients did benefit from pre-HCT chemotherapy [22].

Myelodysplastic syndromes

Presentation and terminology

Approximately 20–25% of individuals with MDS undergoing HCT have antecedent diseases, malignant or non-malignant, for which they received radiation/chemotherapy (secondary or treatment-related MDS); these patients may be rather young. However, for all patients with MDS, the median age at diagnosis is 70–75 years and no etiology can be identified (de novo MDS). "Secondary" MDS is also used to describe MDS evolving from a preceding hematologic diagnosis, for example, aplastic anemia. The pathophysiology of MDS is incompletely characterized [23]. With low-risk or early-stage disease such as refractory anemia (RA) or refractory cytopenia with multilineage dysplasia (RCMD) (Table 54.2), apoptosis, contributing to peripheral blood cytopenias and possibly the containment of the clone(s), is upregulated. In advanced, MDS clonal precursors become increasingly apoptosis-resistant, and proliferative features are prominent. Long considered a cell-autonomous disease, there is evidence for contributions of the microenvironment and immune mechanisms [24].

Most patients with MDS present with anemia, and only few patients with isolated neutropenia or thrombocytopenia. About 40–50% of patients with de novo MDS have clonal chromosomal abnormalities (by classic banding or fluorescent in situ hybridization); as many as 75% or more have clonal chromosomal markers as detected by molecular techniques [25].

Classification systems

The French–American–British classification [26], considering dysplasia and the proportion of myeloblasts, has been replaced by the WHO classification (Table 54.2) [1]; patients with ≥20% myeloblasts are considered to have AML. CMML, as indicated, has been reclassified in a separate MDS/MPN category [27]. These staging systems are used with the IPSS to stratify patients into four prognostic groups [28]. The original IPSS, incorporating cytogenetics, marrow myeloblast count, and blood cytopenias, is being replaced

Table 54.2 WHO classification and criteria for MDS[a]

Classification	Peripheral blood	Bone marrow
Refractory anemia (RA)	Anemia No or rare blasts	Erythroid dysplasia only <5% blasts <15% ringed sideroblasts
Refractory anemia with ringed sideroblasts (RARS)	Anemia No blasts	Erythroid dysplasia only <5% blasts ≥15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Bi- or pan-cytopenia	Dysplasia in ≥10% of cells in two or more myeloid cell lineages
	No or rare blasts No Auer rods Monocytes <1000/μL	<5% blasts No Auer rods <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Bi- or pancytopenia	Dysplasia in ≥10% of cells in two or more cell lineages
	No blasts	<5% blasts ≥15% ringed sideroblasts
MDS-unclassified (MDS-U)	Cytopenias	Unilineage dysplasia in granulocytes or megakaryocytes
	No or rare blasts No Auer rods	<5% blasts No Auer rods
MDS with del(5q) (5q– syndrome)	Anemia	Normal to increased megakaryocytes with hypolobulated nuclei
	<5% blasts Platelets normal or increased	<5% blasts No Auer rods Isolated del(5q)
Refractory anemia with excess blasts1 (RAEB-1)	Cytopenias	Unilineage or multilineage dysplasia
	<5% blasts No Auer rods Monocytes <1000/μL	5–9% blasts No Auer rods
Refractory anemia with excess blasts2 (RAEB-2)	Cytopenias	Unilineage or multilineage dysplasia
	5–19% blasts Auer rods ± Monocytes <1000/μL	10–19% blasts Auer rods ±

[a] In 2008, the WHO added some modifications [1]. A subtype of RARS-T (refractory anemia with ring sideroblasts and thrombocytosis) was recognized, which is often associated with a JAK2 mutation [121]. Patients with persistent cytopenias, lacking sufficient dysplasia, but with typical MDS-associated cytogenetic abnormalities [–7; del(7p); –5; del(5q); t(17q); t(17p); –13; del(13q); del(11p); del(12p)] or rare balanced translocations including t(11;16); t(3;21); t(1;3); t(6;9); inv(3), can be considered under MDS. If only cytopenias are present, these patients are said to have ICUS (idiopathic cytopenia of undetermined significance). Also, RCMD and RCMD-RS are being combined into one group.

Table 54.3 WHO Classification Based Prognostic Scoring System (WPSS) for MDS

Parameters and severity scores

Prognostic parameter	Score			
	0	1	2	3
WHO category	RA, RARS, 5q–	RCMD, RCMD-RS	RAEB-1	RAEB-2
Karyotype[a]	Good	Intermediate	Poor	–
Transfusion requirement[b]	No	Regular	–	–

WPSS risk and outcome

Risk group[c]	Composite score	Survival (years)	AML evolution
Very low	0	11.3	7% at 10 years
Low	1	5.3	–
Intermediate	2	3.7	–
High	3–4	1.6	–
Very high	5–6	0.7	50% at 8 months

[a] Good = normal, –Y, del(5q), del(20q); poor = complex (≥3 abnormalities) or chromosome 7 anomalies; intermediate = other abnormalities.

[b] In a modification (Malcovati et al. [31]), transfusion dependence was replaced by the degree of anemia, with hemoglobin <9 g/dL for men and <8 g/dL for women representing the significant cut-off.

[c] Scores for risk groups as follows: very low = 0, low = 1, intermediate = 2, high = 3–4, very high = 5–6 [30].

by the IPSS-R [7] (Table 54.1). The composite score also considers the *severity* of cytopenias and the new five-group cytogenetic risk classification [29], and stratifies patients into five categories, very low (score ≤1.5), low (>1.5–3), intermediate (>3–4.5), high (>4.5 -6), and very high risk (>6), with median life expectancies of 8.8, 5.3, 3.0, 1.6, and 0.8 years, respectively [7]. Five risk groups also compose the WHO classification-based Prognostic Scoring System (WPSS) (Table 54.3) [30,31], which incorporates transfusion dependence as a risk factor. The five WPSS categories predict median survivals of 11.3, 5.3, 3.7, 1.6, and 0.7 years, respectively. The probability and rate of progression to leukemia increase with increasing scores [7,30]. Marrow fibrosis, flow-cytometric aberrancies, or molecular markers [25,32] are currently not reflected in any classification schemes. Patient age has been included as a risk factor in one scoring system [33].

Transplantation specific risk assessment

Comorbid conditions [34] and a risk score based primarily on pulmonary function [3] have proven to be important tools in determining the probability of transplant success [34–36]. Iron overload (e.g. serum ferritin >1000 or 2000 μg/L; high liver iron content) also are associated with increased NRM and inferior survival [37,38], problems including include increased infection risk and, possibly, sinusoidal obstruction syndrome [39]. No prospective trials are available [40].

Non-transplant therapy and the decision on transplantation

Several treatment modalities other than HCT are available. For patients with a del(5q), lenalidomide (Revlimid) is considered first-line therapy, inducing transfusion independence in two-thirds of patients, for a median duration of 2–2.5 years; many experience morphologic and cytogenetic remissions [41]. Two DNA methyltransferase inhibitors, 5-azacitidine (Vidaza) and 2-deoxy-5-azacitidine (Dacogen), induce hematologic improvement in about half of the patients, and may delay leukemic transformation, and 5-azacitidine prolongs survival by 9–10 months [42]. Therapy with antithymocyte globulin (ATG), alone or combined with other agents, induces hematologic responses in 10–30% of patients with low-risk MDS, lasting in some patients for years [43]. Erythropoietin combined with G-CSF is effective in raising hemoglobin levels in a proportion of patients with low endogenous erythropoietin levels, particularly those with a high proportion of ring sideroblasts [44]. Other therapies are being tested in clinical trials.

The availability of these drugs affects the decision about HCT: should a responding patient be transplanted when a response is achieved or should HCT only be carried out if and when such therapy has failed?

Allogeneic transplantation

Patients with lower risk MDS (by any classification) are generally managed conservatively and HCT is foregone or delayed [4,5] as these patients tend to have a more indolent course. However, isolated manifestations such as severe neutropenia, thrombocytopenia, or red blood cell transfusion dependence may well represent indications for HCT, even though risk scores by IPSS-R may be low (see Table 54.1) [7,37,45–47]. Patients transplanted at an early stage of their disease have superior outcomes. Relapse incidence increases progressively with increasing IPSS or WPSS scores, the major determinants being karyotype and myeloblast count [30,48]. Figure 54.1 illustrates the impact of pre-HCT cytogenetic risk on post-HCT outcome in patients with HLA-matched related or unrelated donors. Similar results have been reported for the impact of WPSS [30]. Some reports of allogeneic HCT in patients with MDS are summarized in Table 54.4.

The International Bone Marrow Transplant Registry (IBMTR) presented results in 452 patients with MDS transplanted from HLA-identical siblings, showing a 3-year RFS of 40% (72% for patients aged ≤18 years); 140 patients (31%) had fewer than 5% blasts at HCT. TRM was 37% and the relapse rate was 23%. High marrow blast counts and high IPSS scores were significantly correlated with relapse. Among 512 patients with MDS transplanted from unrelated donors, those conditioned with high-dose oral busulfan (BU) (1 mg/kg × 16 doses over 4 days) and IV cyclophosphamide (CY) (60 mg/kg/day ×2) fared better than those given high-dose total body irradiation (TBI) (e.g., 6 × 2 Gy) combined with CY [49]. With BU/CY (BU prescribed at 16 × 1 mg/kg), with BU dose adjustment to achieve target steady-state levels of 800–900 ng/mL (targeted BU/CY), investigators at the Fred Hutchinson Cancer Research Center (FHCRC) observed a 3-year RFS of 68% with related donors and 70% with unrelated donors among patients with RA or Refractory anemia with ringed sideroblasts (RARS); the NRM was 31%, and relapse occurred in 5% of patients [48].

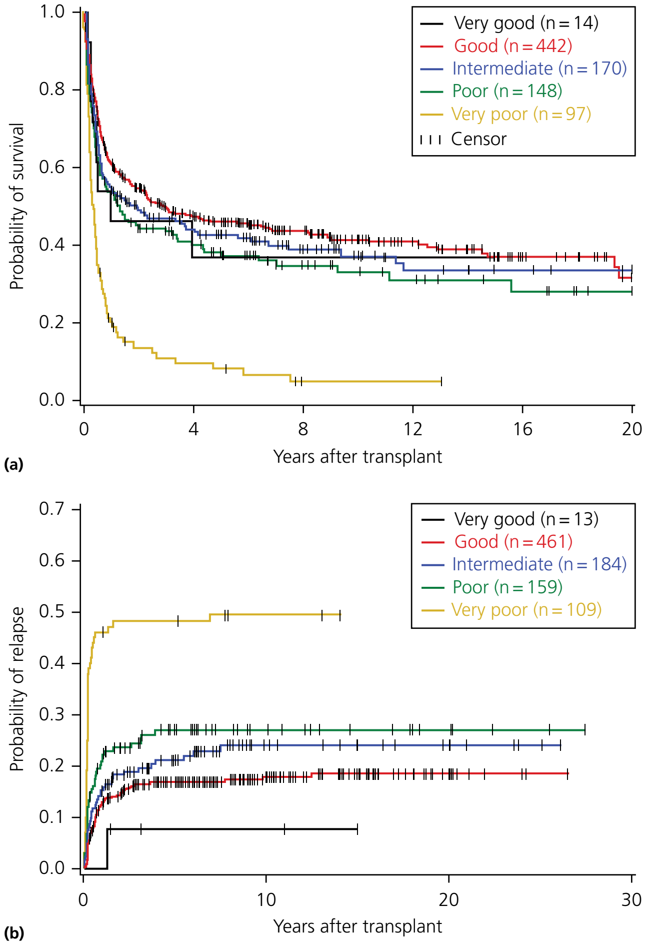

Figure 54.1 Impact of the five-group cytogenetic risk classification (incorporated into the IPSSR) [7,29] on transplant outcome. (a) Surivival. (b) Cumulative incidence of relapse. +, Censored patient. (For a color version of this figure, please see the color plate section.)

Patients with pre-HCT neutropenia tend to have inferior outcomes. Among 469 patients, 178 (61%) with less than 1.5 × 10^9 neutrophils/L had significantly higher NRM ($p = 0.01$), and a lower probability of survival, mostly related to infections [50]. Neutropenia was associated with higher risk karyotype. Iron overload has a negative impact on HCT outcome [37,45–47]. Transfusion dependence is linked to marrow fibrosis, which is associated with more rapid progression of MDS [51]. The potential benefit of chelation therapy remains to be determined [51].

Among 471 patients with MDS undergoing HCT, 113 had marrow fibrosis of various degrees and 358 did not. Patients with marrow fibrosis showed a significant delay in neutrophil and platelet recovery [hazard ratio (HR) 0.4, $p < 0.001$]. Survival, RFS, and NRM between the two groups were similar, but patients at intermediate-2 or high risk by IPSS with marrow fibrosis had greater NRM ($p = 0.04$) and reduced survival ($p = 0.03$) and RFS ($p = 0.04$). Similar results have been reported by others [52].

The success rates of HCT decline as the prognosis by WHO or IPSS criteria worsens, driving factors being marrow myeloblast count and high-risk cytogenetics (Figure 54.1). The EBMT reported a 5-year RFS with related donors of 34, 19, and 26% for refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-T), and therapy-related acute myeloid leukemia (t-AML), respectively; the relapse rate was 50% for the entire cohort. The 2-year RFS for patients transplanted from HLA-matched unrelated donors was 27%, 8%, and 27% for RAEB, RAEB-T, and t-AML, respectively [53]. In a study from FHCRC in patients with RAEB transplanted after conditioning with targeted BU/CY, the 3-year RFS was 45% with related and 40% with unrelated donors. The corresponding figures for RAEB-T/t-AML were 33 and 17%, respectively. The IPSS score correlated strongly with outcome [48].

In an effort to reduce toxicity, the tolerability and efficacy of intravenous fludarabine (4 × 30 to 5 × 50 mg/m^2) have been tested in combination with targeted oral BU [20,54]. The M.D. Anderson team used a regimen of intravenous fludarabine (40 mg/m^2/day) followed by intravenous BU (130 mg/m^2/day) on days −6 to −3 before HCT in patients with advanced myeloid malignancies (22 with MDS). Unrelated recipients also received equine ATG. The 1-year RFS and TRM were 52% and 3%, respectively [20]. Similar data were reported by Russell et al., using intravenous BU (3.2 mg/kg/day for 4 days) and rabbit ATG (Thymoglobulin, 4.5 mg/kg). The addition of 4 Gy TBI to such a regimen reduced the incidence of relapse [55]. Another 37 patients with MDS or t-AML were transplanted after conditioning with fludarabine (120–180 mg/m^2) and reduced-dose BU (8 mg/kg orally or 6.4 mg/kg intravenously) from related ($n = 19$) or unrelated ($n = 18$) donors (Table 54.4). TRM was 27% and 3-year estimated RFS 38%, with a relapse rate of 32% [56]. Whether ATG preparations should be used regularly with RIC regimens has been questioned in recent analyses [57]. The anti-CD52 antibody alemtuzumab was used as part of an RIC regimen for in vivo T-cell depletion. Among 75 patients conditioned with fludarabine/BU/alemtuzumab and given unrelated donor transplants, 3-year survival was 43%. Disease status at HCT and comorbidities were independent risk variables for overall survival [58]. In a prospective phase II study using fludarabine, melphalan, and alemtuzumab in 52 patients with AML and MDS, the relapse incidence

[c] 1° = de novo; 2° = secondary

[d] PB was the stem cell source of choice, but numbers were not provided.

[e] Overall survival.

[f] The focus of this analysis was on the impact of cytogenetics. There was a strong direct correlation for relapse and a reverse correlation of RFS with the new five-group cytogenetic risk classification [29].

was 27%, TRM 33%, and RFS 38%. Disease risk and low performance status were the major adverse factors [59]. Even lower intensity conditioning regimens use TBI doses of 2–4.5 Gy plus fludarabine 3 × 30 mg/m^2, yielding a 2-year survival of 40% in patients with low-risk and 25% in patients with high-risk MDS [60,61]. The addition of iodine-131-labeled anti-CD45 monoclonal antibody for targeted delivery of radiation to hematopoietic cells has intensified the regimen, and may be associated with lower relapse rates [62]. As exportation of the ^{131}I method is challenging, newer protocols are using ^{90}Y, which may lend itself more readily to wider distribution.

In an analysis of results in more than 1000 patients with MDS aged 1–75 years, the impact of the newly established five-group cytogenetic risk classification [29] on outcome after HCT was determined. Patients were transplanted from related (n = 547) or unrelated (n = 460) donors. Cytogenetic risk was significantly associated with relapse and mortality (Figure 54.1). Monosomal karyotype tended to increase rates of relapse and mortality further even after considering the IPSS or five-group classifications. Mortality was also impacted by patient age, donor type, conditioning regimen, platelet count, and etiology of MDS. The best results were obtained with a regimen of fludarabine with treosulfan ± 2 Gy TBI [63,64]. Mortality declined significantly in recent years, despite the fact that patient age increased from a median of 31.7 years before 1990 to a median of 54.3 years in the interval 2006–2010. The proportion of unrelated donor HCT increased from 6 to 57%. There were 254 patients in whom the disease progressed or relapsed after HCT. With a median follow-up of 7.1 years, the 5-year estimates of relapse, NRM, survival, and RFS were 25, 40, 38, and 35%, respectively.

Hence the success of HCT in patients with MDS is determined primarily by the proportion of myeloblasts in the marrow and the karyotype. An additional important factor is patient co-morbidities (discussed in Chapter 28). Depending on these parameters, as many as 70–80% or as few as 15–20% of patients may be cured by HCT; some patients have been followed now for more than 25 years after HCT. Results with unrelated donors who are HLA matched by high-resolution typing are comparable to those with HLA genotypically identical sibling donors. Data with cord blood or HLA-haploidentical transplants are emerging.

Secondary/treatment-related MDS

Friedberg et al. analyzed outcomes in 552 patients after autologous HCT for non-Hodgkin lymphoma, 41 of whom developed MDS at a median follow-up of 47 months, for an incidence of 19.8% at 10 years [65]. None of the 13 patients who received allogeneic HCT survived long term. Yakoub-Agha et al. reported results in 70 patients with secondary MDS or t-AML [19], who received allogeneic HCT following conditioning with high-dose TBI or BU-containing regimens. RFS at 2 years was 28% for the entire cohort, 45% for patients in complete remission, and 18 and 26% for patients with active MDS and t-AML, respectively. Woodard et al. [66] presented results in 38 children given allogeneic HCT for secondary MDS. Overall survival and RFS were similar at 15.4% at 3 years; NRM was 60% and relapse incidence 24%. The proportion of marrow blasts at the time of HCT was the strongest risk factor for relapse.

In an FHCRC analysis of 257 patients aged 3–72 years (median 43 years) and with secondary MDS, the rate of HCT success was similar to that with de novo MDS when adjusted for risk factors, in particular cytogenetics. The five-year RFS was 43% and NRM 28% among patients conditioned with targeted BU/CY. The relapse incidence was lower (p = 0.003) and RFS superior (p = 0.02) with unrelated donors. Litzow et al. summarized CIBMTR data on 868 patients with treatment-related MDS or AML [67], and showed an NRM at 1 year (5 years) of 41% (48%) and a relapse incidence of 27% (31%). The 5-year RFS was 21%. Older age, high-risk cytogenetics, AML not in remission or advanced MDS, and the use of HLA non-identical donors were the major risk factors, with 5-year survivals of 50, 26, 21, 10 and 4% among patients with no, one, two, three, or four risk factors, respectively (Figure 54.2). The impact of cytogenetics was not reported.

The search for the ideal regimen

The RIC regimens discussed have the advantage of low regimen-related toxicity, allowing their use in older patients or patients with severe comorbid conditions [68,69]. The disadvantage (in MDS) is higher relapse rates [70–73]. An ongoing Blood and Marrow Transplant Clinical Trials Network (BMT CTN)-sponsored phase III trial is comparing toxicity and efficacy of high-intensity and RIC regimens in patients with MDS or high risk AML (BMT CTN protocol 0901). A large retrospective study by the EBMT group in 836 patients with MDS given various high-dose (n = 621) or RIC regimens (n = 215) showed no significant difference in survival; relapse rates were significantly lower in patients receiving high-dose conditioning, but this advantage was canceled out by a higher TRM [74]. An updated analysis of results in patients more than 50 years of age, basically confirmatory, showed that disease stage was the determining factor for outcome. Age had a minor effect, and results were comparable for RIC and high-intensity regimens [21] (Figure 54.3).

More conventional high-intensity regimens also have been progressively modified, aiming at low toxicity combined with high efficacy. Encouraging results have been observed with regimens incorporating treosulfan [75,76]. In a trial conducted at FHCRC, 60 patients (primarily with MDS or AML) were conditioned with fludarabine (30 mg/m^2 × 5) plus treosulfan (12 or 14 g/m^2 × 3) [63]. NRM by 1 year was less than 10%, and 2-year survival for patients with standard- or intermediate-risk cytogenetics was 80%. Patients with high-risk karyotype, in contrast, showed long-term RFS of 35–40%, the difference being due primarily to a higher relapse incidence. Preliminary data from a successor protocol in which 2 Gy of TBI was added to fludarabine/treosulfan suggested that this combination reduced the relapse risk even in patients with high-risk cytogenetics, although the frequency of toxicity (skin rashes and mild mucositis) was increased [64].

MDS in children

MDS is rare in children, accounting for 5–7% of hematologic malignancies. There are similarities to but also major differences from MDS in adults, and a separate classification has been proposed (Table 54.5) (the MDS/MPN group is discussed in Chapter 51). Patients with Down syndrome who developed MDS/leukemia are no longer considered in the MDS category.

Children with MDS present with thrombocytopenia or neutropenia more frequently than with anemia, and the term "refractory cytopenia of childhood" (RCC) is preferred. Also, the category of RAEB-T has been retained [77]. About 50–60% of the patients have clonal cytogenetic abnormalities, the most frequent one being monosomy 7 (in ~25% of cases). In patients with monosomy 7, the disease progresses faster than with other karyotypes. In secondary MDS, as in adults, about 80% of patients have cytogenetic abnormalities [78]. In contrast to adults, however, about 75% of children with MDS have hypocellular marrows, and the distinction from aplastic anemia may be difficult. In fact, about 10–15% of children with aplastic anemia develop MDS within 3 years, and "aplastic anemia" may simply be the initial presentation of MDS.

Chemotherapy is not useful in pediatric MDS, and HCT should be considered early in the course. Several studies have been reported from Europe, Japan, and the United States. Kardos et al. [79] reported on 67 children, 41 of whom underwent allogeneic HCT. Among children in whom the disease had not progressed from refractory cytopenia, 76% were surviving, compared to 36% with advanced MDS (>5% myeloblasts). Sasaki et al. [80] presented data on 189 patients [122 primary MDS, 24 with constitutional predisposition (see Chapter 75) and 43 with therapy-related MDS]. The 4-year survival among patients with refractory cytopenia was 79%, compared with less than 40% in all other patients. Children who underwent HCT had a significantly higher survival probability. Yusuf et al. reported results in 94 children receiving allogeneic HCT for MDS [81]. The 3-year probabilities of NRM, relapse, and RFS were 28, 29, and 41%, respectively. RFS was 74% in patients with refractory cytopenia, 68% with RAEB, and 33% with juvenile myelomonocytic leukemia. Patients with RAEB-T were 5.5 times more

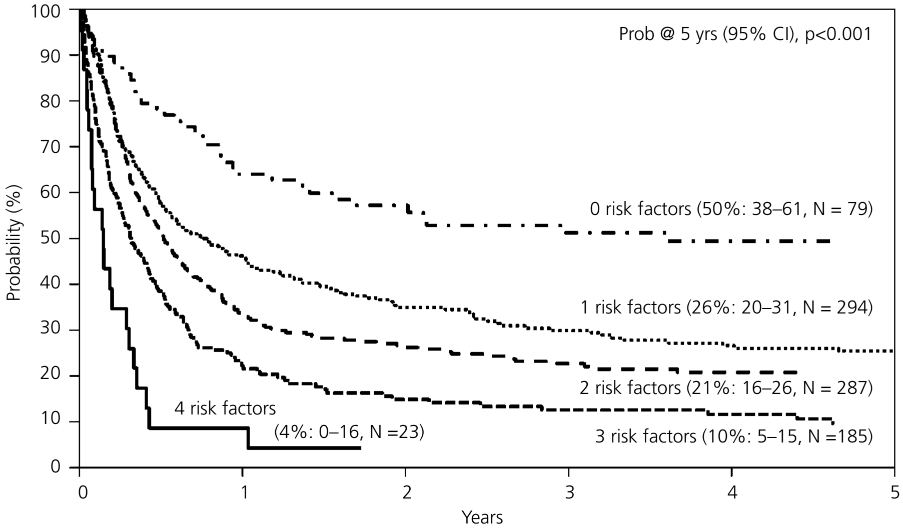

Figure 54.2 Probability of overall survival after allogeneic HCT for therapy-related AML and MDS, by risk factors: age older than 35 years; poor-risk cytogenetics; t-AML not in remission or advanced t-MDS; donor other than an HLA-identical sibling or well-matched unrelated donor. Table 54.5 Classification of MDS and MDS/MPN of childhood

I. MDS/MPN
  - Juvenile myelomonocytic leukemia
  - Chronic myelomonocytic leukemia (secondary only)
  - BCR-ABL-negative chronic myeloid leukemia

II. Down syndrome disease
  - Transient abnormal myelopoiesis
  - Myeloid leukemia of Down syndrome

III. MDS
  - Refractory cytopenia (peripheral blood blasts <2% and marrow blasts <5%)
  - Refractory anemia with excess blasts (RAEB) (peripheral blood blasts 2–19% or marrow blasts 5–19%)
  - RAEB in transformation (RAEB-T) (peripheral blood or marrow blasts 20–29%)

likely to relapse than other patients. More recently, Parikh et al. [82] presented results in 23 patients transplanted with umbilical cord blood cells. Children were aged 1.6–12.4 years (median 5.3 years) and had RA (*n* = 12), RAEB (*n* = 8), or RAEB-T (*n* = 3). Donors were matched for HLA at 4/6 antigens in 16 cases and 5/6 antigens in seven cases. Most patients were conditioned with TBI-based regimens; 0.2–28.5 (median 1.7) × 10^5 CD34$^+$ cells/kg were infused. All but three patients engrafted, albeit with very delayed platelet recovery, and RFS at 1 and 3 years was 70 and 61%, respectively. Causes of death, in addition to graft failure, included relapse (*n* = 4), infections (*n* = 2), and a lymphoproliferative disorder (*n* = 1). Factors associated with superior survival were younger age (p = 0.05) and lower body weight (p = 0.03).

Myeloproliferative neoplasms

The scope of MPN, presentation, and staging

The second category of chronic myeloid disorders is known as myeloproliferative neoplasms (MPNs). MPNs include chronic myeloid leukemia (CML) (discussed in Chapter 48), polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF). According to the WHO classification, other, rare disorders such as chronic neutrophilic leukemia, chronic eosinophilic leukemia (and hypereosinophilic syndrome), and chronic myeloproliferative diseases, unclassifiable, are included in the MPN category (mast cell disorders are classified separately) [27].

Patients with PV or ET in many instances have a rather indolent course over decades, until they develop severe marrow fibrosis and splenomegaly, along with peripheral blood cytopenias, or progress to acute leukemia. Patients with PMF present with marrow fibrosis, may have leukocytosis or elevated platelet counts, and generally proceed to develop single- or multilineage peripheral blood cytopenias. In 2005, an activating mutation (V617F) in the JAK-2 kinase was identified in >95% of patients with PV, and about half of the patients with ET or PMF [83]. This mutation contributes to the disease, but recent findings indicate that other mutations, for example in TET2, precede the JAK2 mutation, and the development of leukemia not showing the JAK2 clone in patients previously JAK2 (V617F)-positive patients, supports that concept. Also, additional mutations have been identified, for example, in exon 12 of the gene or in the *Mpl1* gene, that contribute to the disease [84,85].

Patients with MPN also develop complications in nonhematopoietic organs, including hepatic fibrosis, portal hypertension, heart failure, and infectious complications due to cytopenias [86]. Several prognostic scoring systems have been developed for PMF, and are also applied to patients with PV or ET once they develop marrow fibrosis. The Lille (or Dupriez) score has been replaced by the DIPSS, which considers patient age, hemoglobin levels, leukocyte count, circulating myeloblasts, and patient symptoms, and on that basis distinguishes four risk groups (Table 54.6) with median life expectancies not yet reached (at the time of reporting) for the good-risk group, and 14.2, 4, and 1.5 years, respectively, for the remaining three risk groups. In a refinement (DIPSS-plus) [87], platelet counts less than 100,000, cytogenetic abnormalities such as +8, −7/7q−, i(17q), −5/5q−, 12p−, inv(3), 11q23, and complex karyotype, and transfusion dependence, have been added as risk factors (see Table 54.6).

Non-transplant therapy

Hydroxyurea and interferon (IFN) are time-honored modalities of treatment for MPN. A pegylated form of IFN is better tolerated than older preparations of IFN, leading to gratifying responses in spleen size reduction and blood cell counts [88]. IFN may also lead to regression of marrow fibrosis. However, with the identification of the JAK2 (V617F) mutation, the focus has been on "JAK2 inhibitors," and one preparation, ruxolitinib (Jakafi), has been approved by the US Food and Drug Administration (FDA) for patients with intermediate- and high-risk MPN. Major benefits have been improvement or resolution of patient symptoms (such as night sweats or bone pain) and regression of spleen size [89,90]. Although not without controversy, at least one randomized trial suggested prolongation of survival [89]. Additional JAK2 inhibitors with different clinical profiles are currently being investigated. The availability of these agents is leading to discussions similar to those on hypomethylating agents in patients with MDS, and how the use of those agents may impact the decision about HCT. It will be important to monitor patients closely; there have been patients whose symptoms improved while the disease actually progressed, as indicated by rising blast counts. Other agents include thalidomide and pomalidomide that may improve anemia or anagrelide for the control of high platelet counts.

Transplantation for PMF, PV, and ET

Most patients with PV or ET are considered for HCT when they develop peripheral blood cytopenias or their disease progresses to myelofibrosis or AML develops. In PMF, indications for HCT are typically peripheral blood cytopenias or evidence of leukemic transformation. Splenectomy does probably not significantly alter the course of the disease [8,52]. Marrow fibrosis by itself does not interfere with engraftment of donor cells [91,92].

Table 54.6 Risk factors in PMF in the DIPSS classification[a] [126]

Risk factors		
Age >65 years	DIPSS	DIPSS-plus
Constitutional symptoms		
Hemoglobin <10 g/dL		
WBC count >25 × 10^9/L		
Blood myeloblasts >1%		
Platelet count <100 × 10^9/L		
Abnormal cytogenetics		
Transfusion dependency		

DIPSS risk categories and survival

Risk group	No. of factors	Proportion of patients (%)	Median survival (months)
Low	0	22	135
Intermediate-1	1	29	95
Intermediate-2	2	28	48
High	≥3	21	27

DIPSS-plus categories and survival

Risk group	Risk score	Median survival (months)
Low	0	180
Intermediate-1	1	80
Intermediate-2	2–2	35
High	4–6	16

DIPSS, Dynamic International Prognostic Scoring System.

[a] Unfavorable karyotype: complex karyotype or sole or two abnormalities that include +8, –7/7q-, i(17q), –5/5q1, 12p–, inv(3), or 11q23 rearrangement. DIPSS-plus is derived from the DIPSS by weighing: one point is added for intermediate-1 risk (by DIPSS) and for platelet counts <100 × 10^9/L, unfavorable cytogenetics, and red cell transfusion need, respectively; DIPSS intermediate-2 receives two points and DIPSS high receives three points.

Ballen et al. reported results in 289 patients with PMF, 18–73 years old, transplanted from HLA-identical siblings (n = 162), unrelated individuals (n = 101), or HLA non-identical family members (n = 26) [93]. Splenectomy had been performed in 65 patients. The day 100 mortality was 18, 35, and 19% and 5-year RFS was 33, 27, and 22% for the three donor groups, respectively.

Outcome data on 170 patients from FHCRC with PV, ET, or PMF, 12–78 years of age, transplanted from allogeneic (83 related, 84 unrelated) or syngeneic (n = 3) donors were recently presented [8]. Most patients (n = 106) received targeted BU/CY (combined with ATG in 15) for conditioning. Other regimens included intravenous fludarabine, 3×30 mg/m^2, and 2 Gy of TBI in 13 patients (see Chapter 21); in 18 patients CY was administered first, followed by BU, thereby avoiding altered CY metabolism (and toxicity) due to BU-induced enzyme activation. Most patients (n = 125) received PBPCs, and 45 received marrow. Eight of 167 allogeneic recipients experienced graft rejection/failure. The 5-year estimate of relapse/disease progression was 10%, and NRM was 34%. With a median follow-up of 5.9 years, the median survival was not reached for patients with low or intermediate-1 risk by DIPSS (survival estimated at 80 and 65%, respectively) and was 7 and 2.5 years for patients with intermediate-2 and high-risk disease, respectively [8]. The best tolerated regimen was the CY followed by BU combination, with a day 100 mortality of 0%. The overall and NRM (but not relapse by itself) increased significantly with DIPSS stage, presumably a reflection of the fibrosis affecting non-hematopoietic tissues (Figures 54.4 and 54.5). Low hemoglobin values had the most profound impact on outcome ($p < 0.001$ for overall mortality, "relapse or death" and NRM), consistent with the added factor "transfusion dependence" in the DIPSS-plus. Among parameters not included in the DIPSS, there was a suggestion that splenectomy was associated with reduced mortality ($p = 0.05$), a finding that must be interpreted with caution since the transplant center had no control over who underwent splenectomy and, in fact, another report suggested an inferior success rate in splenectomized patients [94]. The major causes of death were related to GVHD, infections, relapse, and graft failure. When adjusted for disease risk, the results show a clear improvement of transplant results in more recent years.

Ditschkowski et al. presented results in 76 patients with PMF (n = 47) or myelofibrosis after PV or ET (n = 29), transplanted from related (n = 30) or unrelated (n =4 6) donors [9]. The 1-year NRM was 28% and RFS was 50%, with a relapse rate of 19% at 5 years. Cytotoxic therapy pre-HCT (and the development of chronic GVHD) were adverse risk factor for survival. Patients in the DIPSS risk group "low" had significantly superior RFS ($p = 0.02$) compared with higher risk groups. The inclusion of the DIPSS-plus allowed four risk groups to be discriminated with 5-year survival probabilities of 100, 51, 54, and 30%, respectively. Relapse was significantly increased in patients without chronic GVHD.

Rondelli et al. presented data on 21 patients aged 27–68 years (median 54 years) with intermediate- or high-risk myelofibrosis (based on the Lille score) transplanted over an extended time interval, using several RIC regimens. All but one patient engrafted, and 18 patients were alive (17 in remission) with a median follow-up of 31 months [95].

Kröger et al. presented data from a prospective study in 103 patients aged 32–68 years (median 55 years) with PMF or fibrosis

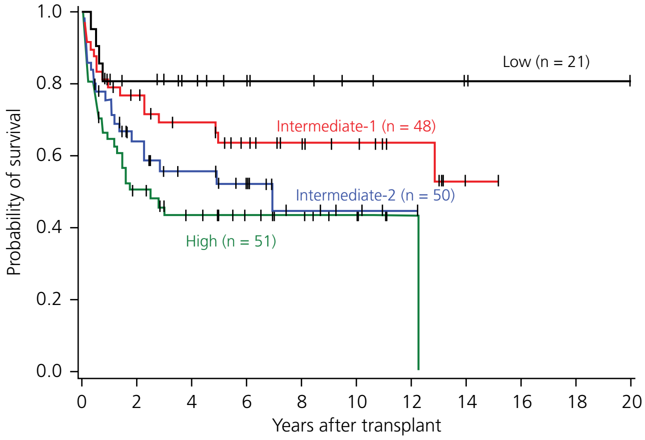

Figure 54.4 Overall survival of patients with PMF or myelofibrosis developing from PV or ET, by DIPSS category. Source: Scott et al. 2012 [8]. Reproduced with permission of the American Society of Hematology.

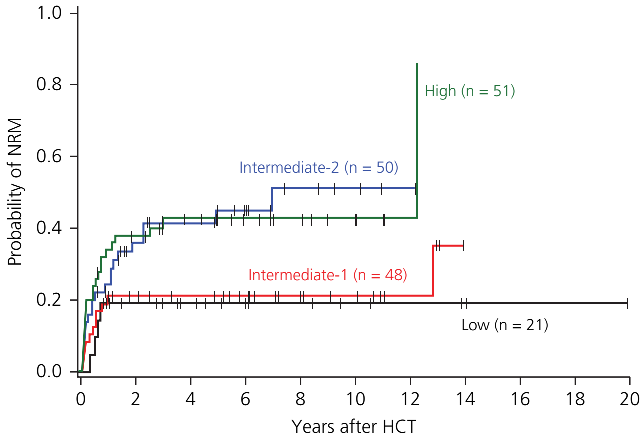

Figure 54.5 Non-relapse mortality of patients with PMF or myelofibrosis developing from PV or ET, by DIPSS category. Source: Scott et al. 2012 [8]. Reproduced with permission of the American Society of Hematology.

after PV or ET, conditioned with BU 10 mg/kg, plus fludarabine 180 mg/m^2 and ATG, and transplanted from related or unrelated donors [52]. Two patients failed to achieve leukocyte and platelet engraftment. NRM at 1 year was 16%, significantly lower in recipients of HCT from completely HLA-matched donors (12% vs. 38%, p = 0.003). The relapse incidence was 22% at 3 years and correlated with the Lille score. The estimated 5-year RFS was 51%. Age older than 55 years (HR 2.70) and HLA-mismatched donors (HR 3.07) were significant risk factors for survival. Investigators at City of Hope Medical Center presented results on nine patients aged 46–68 years (median 54 years). Eight patients received fludarabine 25 mg/m^2/day for 5 days followed by melphalan 140 mg/m^2 for conditioning, while one patient received fludarabine 30 mg/m^2 for 3 days followed by 2 Gy TBI. All patients achieved engraftment, and the probability of 1-year survival was 56% [96].

An RIC regimen of fludarabine 90 mg/m^2 plus 2 Gy TBI yielded a survival rate of 56%, which did not differ from that achieved with higher dose regimens. However, this small cohort consisted of patients up to 70 years of age, most of whom had comorbid conditions [2]. Conceivably, conditioning regimens of intermediate intensity will offer the best outcome [97].

An analysis of results in 139 patients with advanced myelofibrosis, with known JAK2 status who were transplanted following RIC, showed a significantly inferior overall survival among those with wild-type JAK2 (HR 2.14, p = 0.01); allele burden did not appear to affect outcome among patients with mutated JAK2 [98]. However, in the study of 170 patients discussed above, who were conditioned with various regimens, there was a trend for inferior survival among patients with mutated JAK2 [8].

While generally HCT has been carried out for patients with PV or ET only when they developed marrow fibrosis or there was evidence of leukemic transformation, a recent analysis described 119 patients with PV or ET who were transplanted for various reasons [99]. Most patients received high-intensity conditioning; donors were HLA-identical siblings in 32 and unrelated individuals in 87 patients. The 1-year NRM was 27% for ET and 21% for PV patients, and the 5-year relapse incidence was 12 and 32%, respectively. Overall survival (RFS) at 5 years was 56% (48%) and 67% (47%) for ET and PV patients, respectively. As in all other studies, platelet and neutrophil recovery was significantly faster in patients with normal spleen size or after splenectomy.

Taken together, the results show that HCT provides effective therapy for patients with PMF, PV, or ET. Once leukemic transformation occurs, the probability of a successful HCT declines significantly to about half of what is achievable with earlier HCT.

Other MPNs

Experience with HCT for patients with chronic neutrophilic leukemia, chronic eosinophilic leukemia (hypereosinophilic syndrome), and unclassified MPN is very limited. The optimal therapy for chronic neutrophilic leukemia is not known. However, because of the potential for blastic transformation, HCT has been considered appropriate therapy, particularly for young patients [100]. Similarly, successful HCT has been reported in patients with chronic eosinophilic leukemia [101,102]. The recognition that about 10% of patients with this disorder have an interstitial deletion on chromosome 4q12 that leads to the expression of an FIP1L1–PDGFRα fusion gene with tyrosine kinase activity has made treatment with tyrosine kinase inhibitors an attractive alternative [103]. About 70–80% of these achieve complete remissions with imatinib [104,105]. Several patients with unclassifiable MPN have also been transplanted successfully [8,91].

Myelodysplastic/myeloproliferative neoplasms

The WHO has listed CMML, atypical CML, juvenile monocytic leukemia, and unclassifiable MDS/MPN as a separate category. As implied by the terminology, these disorders show both dysplastic and proliferative features [106].

Chronic myelomonocytic leukemia

Persistent peripheral blood monocytosis (>1000/μL) is the hallmark of CMML. Depending on the myeloblast count, CMML is divided into CMML-1 (blood <5%, marrow <10%) and CMML-2 (blood 5–19%, marrow 10–19%). The WHO has also defined a separate category of CMML with eosinophilia when there is an accompanying peripheral blood eosinophilia. Patients in this category, representing a small proportion of patients with CMML, often have a t(5;12)(q33;p13) translocation, which results in an abnormal platelet-derived growth factor receptor fusion gene, and those patients are likely to respond to tyrosine kinase inhibitors

Table 54.7 M.D. Anderson criteria for CMML risk category

No. of risk factors[a]	Risk group	Median survival (months)
0–1	Low	24
2	Intermediate-1	15
3	Intermediate-2	8
4	High	5

[a] Risk factors: hemoglobin <12 g/L; absolute lymphocyte count >2.5 × 10^9/L; immature myeloid cells circulating in peripheral blood; ≥10% myeloblasts in bone marrow [107].

[106]. Other clinical features include splenomegaly, lymphadenopathy, and skin rashes. The M.D. Anderson group has developed a scoring system for CMML based on four clinical parameters: hemoglobin <12 g/L, the presence of circulating immature myeloid cells, an absolute lymphocyte count of over 2.5 × 10^9/L, and marrow myeloblasts over 10% predict a poor prognosis (Table 54.7). Based on the presence of one or several of those findings, patients are divided into low, intermediate-1, intermediate-2, and high-risk categories, with median survivals of 24, 15, 8, and 5 months, respectively, in patients who are not transplanted [107].

Despite the term "chronic," CMML can show fairly rapid progression to acute leukemia. About half of the patients with transformation will achieve complete remissions with intensive induction chemotherapy. On average, remissions are sustained for 4–5 months. Thus, except for patients with a t(5;12) translocation, the majority of whom will respond to tyrosine kinase inhibitors, the only promising therapy is HCT.

An EBMT series reported transplant results in 50 patients, about half of whom were conditioned with TBI-based regimens (n = 26). Most patients (n = 38) were transplanted from HLA-matched siblings. Forty patients received marrow, nine received PBPCs, and one received both. RFS at 2 years was 18%, with an NRM of 55% and a relapse incidence of 42%. Patients who developed acute GVHD had a lower rate of relapse [108]. A report from FHCRC included 86 patients , 1–69 years of age, 38 transplanted from related and 47 from unrelated donors [35]. The source of stem cells was marrow in 32 and PBPCs in 53 patients. Sustained neutrophil engraftment was achieved in 91% of the patients; however, 18 patients died between days 11 and 115 without having achieved platelet reconstitution. The major causes of death were relapse and infections ± GVHD; the relapse incidence at 10 years was 27% and RFS was 38%, Mortality was increased with low pre-HCT hemoglobin (p = 0.007), high-risk cytogenetics (p = 0.02), higher HCT-CI (p = 0.0008), and older age (p = 0.02). Survival at 10 years was 53% in patients with HCT-CI 0–2 and 27% with HCT-CI ≥3 (Figure 54.6). Outcome did not correlate with the WHO classification or with any other currently used classification system.

Atypical CML

Atypical CML is a rare disorder with poor prognosis. Koldehoff et al. reported results with HCT in nine patients (four transplanted from HLA-identical siblings, four from HLA-matched unrelated donors, and one from an identical twin brother) [109]. One patient died at 9 months from cerebral toxoplasmosis. The remaining patients are alive and in remission (the twin transplant recipient after a second HCT from the same donor following relapse) at a median of 55 months after HCT. These data suggest that HCT offers curative therapy for patients with atypical CML.

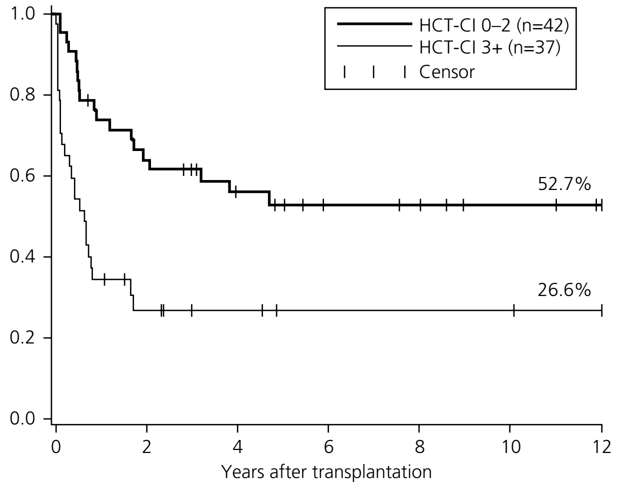

Figure 54.6 Survival dependent upon pre-transplant comorbidities. Shown are the probabilities of survival for 42 patients with HCT-CI scores 0–2 (52.7%) and for 37 patients with scores of ≥3 (26.6%). Source: Eissa et al. 2011 [35]. Reproduced with permission of Elsevier.

Juvenile myelomonocytic leukemia

Studies in patients with juvenile myelomonocytic leukemia are described in Chapter 49.

Systemic mastocytosis

The WHO has classified mast cell disorders in a separate category [27]. Patients with indolent mastocytosis have an excellent prognosis. However, patients with aggressive systemic mastocytosis or mast cell leukemia may have a life expectancy of only 1 year or less [110]. Nakamura et al. reported on three patients who were transplanted from HLA-identical siblings, following conditioning with an RIC regimen [111]. All patients achieved engraftment; however, all experienced disease progression, with the longest response interval being 39 months. Sperr and co-workers reported a successful HCT following high-intensity conditioning in an 18-year-old boy with myelomastocytic leukemia [112,113]. Other successful HCTs for mastocytosis have been reported by Hennessy et al. [114] and Przepiorka et al. [91].

Autologous HCT

Several reports have shown potential benefits and even cure with autologous HCT in patients with MDS and MPN. However, successes have been few, and with the development of various conditioning regimens and the availability of many allogeneic donor options, autologous HCT is currently not a recommended strategy for these patients.

Relapse after HCT

Post-HCT relapse has remained a challenging problem, particularly in patients with MDS. Discontinuation of GVHD prophylaxis (or therapy) and the infusion of viable donor lymphocytes can induce remissions in a small proportion of patients. A prospective trial in pediatric patients tested the efficacy of preemptive donor lymphocyte infusion in 65 patients with refractory cytopenia or advanced MDS who showed mixed chimerism with increasing proportions of host cells after allogeneic HCT [115]. Sequential chimerism testing showed that 48 patients became complete chimeras, and five had increasing proportions of donor cells, while 12 continued to show increasing numbers of host cells. RFS was 50%, compared with 0% in historical controls not treated with donor lymphocyte infusions. However, in a study of 194 adult patients with MDS or acute or chronic leukemia, originally conditioned with high-dose or RIC regimens, only 20–30% achieved complete remission following discontinuation of immunosuppression or donor lymphocyte infusion. Further, 2-year survival was 0–4% for patients who had relapsed within 100 days of HCT, and 5–12% if the relapse occurred after day 100 [116]. Platzbecker et al. monitored CD34 chimerism post-HCT and initiated treatment with 5-azacitidine when donor CD34 chimerism declined to <80% [117]. Among 20 patients so treated, four (20%) achieved complete and sustained remissions and a further six (30%) achieved major hematologic responses, which, however, were not sustained. Second transplants, particularly with RIC regimens, are an option. However, the success rates have been low, related to NRM or refractoriness of the disease [118]. Ongoing studies are investigating whether adjuvant or preemptive therapy, in particular with DNA methyltransferase inhibitors [119], may reduce the relapse incidence in high-risk patients. Other strategies include the infusion of donor natural killer (NK) cells, T cells sensitized against patient leukemia cells, or vaccination approaches.

GVHD

GVHD is common after allogeneic HCT for MDS or MPN. The incidence of acute GVHD has been reported in the range 25–70%, typically somewhat higher for unrelated than for related donor HCT, and chronic GVHD occurs in a similar proportion of patients. The incidence is higher with the use of PBPCs than with marrow, not only for related but also for unrelated donor HCT [10]. Although survival rates have been similar, the impact of chronic GVHD on quality of life cannot be neglected.

Conclusions and perspective

The past 15 years have seen major developments with regard to optimizing conditioning regimens with the goal of reducing regimen-related toxicity and mortality without increasing the risk of relapse. One basic principle has been the reduction of cytotoxic intensity in favor of regimens focused on immunosuppression, sufficient to allow donor cells to become established and rely on donor cell-mediated allo-immune effects to eradicate the patient's disease. With this strategy, it is essential to consider both pre- and post-HCT treatment modalities in the overall approach to HCT (e.g., patients with MDS who have received little or no cytotoxic therapy before HCT may be at higher risk of graft failure and disease recurrence than patients with AML who received aggressive induction chemotherapy) (Figure 54.7) [61,74].

HCT is the only currently available treatment with curative potential for patients with MDS and MPN. The prognostic scoring systems discussed here are helpful in deciding which patients should be transplanted and provide a guide to the optimum timing. Results from controlled prospective trials comparing different intensity regimens are currently not available, although one such study is under way in patients with AML or MDS and l<5% marrow myeloblasts at the time of HCT (BMT CTN protocol 0903). Retrospective studies have generally failed to show significant differences between results obtained with different intensity conditioning regimens, possibly related to the fact that the selection of a conditioning regimen was subject to selection bias. Typically, older patients who appear biologically younger and have no major comorbid conditions will undergo HCT. Also, often the response to pre-HCT therapy will be a factor leading to the decision to proceed to HCT whereas patients whose disease shows no response will not.

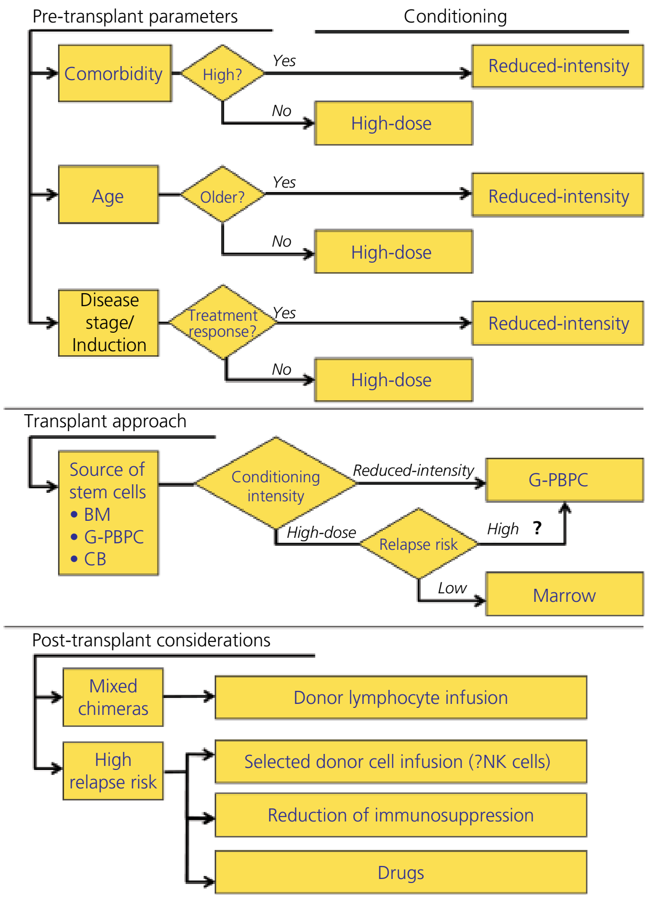

Figure 54.7 HCT for patients with MDS and MPD is an evolving field. This algorithm provides some guidance regarding consideration of patient age, comorbid conditions, disease stage (and the possible advisability of induction therapy) when deciding upon a conditioning regimen. For patients with high-risk disease and with reduced-intensity/non-myeloablative transplant regimens, G-CSF-mobilized peripheral blood progenitor cells (G-PBPCs) are currently the preferred source of stem cells. Post-transplant manipulations depend upon the type of transplant, the degree of donor cell chimerism that is achieved, and the remission status. BM, bone marrow; CB, cord blood; NK, natural killer.

We need novel strategies to overcome the hurdle of high-risk cytogenetics; targeted approaches with radioimmunotherapy may be such a modality. As multiple genomic mutations in clonal hematopoietic precursors are being identified in MDS and MPN, these mutations are likely to be incorporated into new classification schemes. Further, the impact of these mutations on transplant outcome will need to be determined and therapeutic compounds targeting the pathways affected by these mutations will have to be developed. As new agents for non-HCT therapy become available, the question of timing of HCT will have to be readdressed [120].

General aspects of myeloma

Epidemiology and etiology of myeloma

Multiple myeloma (MM) is a clonal disorder of plasma cells affecting approximately 50,000 people in the United States, with an annual incidence of about 15,000 new cases. Median age of onset is 72 years, and it is rarely seen in patients under the age of 40 years. Men are slightly more commonly affected than women, and African-Americans have nearly twice the incidence of Caucasians. Thus MM represents a relatively common hematologic disorder and has emerged as the most common indication for stem-cell transplantation (SCT) today in most of the world [1,2].

Although the causes of myeloma are not known, there is evidence that the pathogenesis of myeloma is a multistep process. The disease often evolves from a premalignant condition called monoclonal gammopathy of undetermined significance (MGUS) [3]. Clonal plasma cell proliferation in MGUS is triggered by translocations involving the immunoglobulin heavy chain (IgH) locus on chromosome 14q32 [4]. Secondary genetic abnormalities involving other oncogenes and tumor suppressor genes (e.g., *ras*, *p53*, *RB-1*) and changes in the bone marrow microenvironment are believed to play a role in the evolution of MGUS into MM [4,5]. No common molecular pathway for transformation has yet been described [6].

Molecular and cellular biology

The malignant plasma cell migrates from the germinal centers of the lymph nodes to the bone marrow, which provides a microenvironment conducive to terminal plasma cell differentiation [6,7]. Malignant transformation in MM appears to start with genetic abnormalities late in B-cell differentiation [8–10]. The presence of genetic abnormalities have been demonstrated by fluorescence in situ hybridization (FISH), comparative genomic hybridization (CGH), and gene expression profiling (GEP) in most patients with MM [10].

The evolution from normal to malignant plasma cells has been extensively reviewed elsewhere [11]. In brief, in an early stage of MGUS or smoldering MM, critical chromosomal abnormalities may occur, leading to one of the five known IgH translocations.The five recurrent IgH translocations seen in MGUS and MM involve these chromosomal partners: 4p16, 6p21, 11q13, 16q23, and 20q11. The identified genes include cyclin D1 and other growth factors (11q), the fibroblast growth factor receptor 3 (4p), the basic zipper C-MAF transcription factor (16q), and interferon (IFN) regulatory factor 4 (6p). The IgH translocation increases the expression of an oncogene that is positioned near a strong immunoglobulin enhancer. The malignant clone derived from the transformed cell is capable of further differentiation and division. During the evolution of MM to advanced stages, additional genetic events, including loss of chromosome 13, activation of other oncogenes such as *Ras*, loss of tumor suppressor gene *p53* and *Rb*, and dysregulation of the cell cycle may take place. Once in the bone marrow, myeloma and stromal cells generate a supportive microenvironment with a network of cytokines and adhesion molecules that promote MM proliferation and perpetuation by promoting growth and preventing apoptosis. Increased osteoclast activation, likely mediated by increased levels of macrophage inflammatory protein 1 (MIP-1) and receptor activator of nuclear factor kappa B ligand (RANKL), and decreased levels of osteoprotegerin (OPG), the decoy receptor for RANKL, results in lytic bone lesions and osteoporosis [11].

Clinical description

Bone pain affects approximately 70% of all myeloma patients [12], the pain generally being localized to the back and ribs. The bone lesions of myeloma are caused by the proliferation of tumor cells and the activation of osteoclasts that destroy the bone. The bone destruction results in severe bone pain, pathologic fractures, hypercalcemia, and nerve compression syndromes. A unique feature of myeloma bone lesions is that the lesions rarely heal even when the patient is in complete remission (CR) [12–14].

Recurrent bacterial infections constitute another common clinical problem in myeloma. The most common infections are pneumonias and pyelonephritis, and the most frequent pathogens are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Klebsiella pneumoniae* in the lungs and *Escherichia coli* and other Gram-negative organisms in the urinary tract. The susceptibility to infection has several contributing causes, including suppression of normal antibody synthesis, poor antibody response to polysaccharide antigens, and abnormalities in granulocyte and complement functions [15].

The serum creatinine level is elevated in almost 50% of patients and renal failure is seen in about 25% of patients. Many factors contribute to renal dysfunction, including hypercalcemia, hyperuricemia, amyloid deposition, and recurrent infections. However, tubular damage associated with light-chain excretion is the predominant cause [12,16]. Anemia is present in 80% of patients at diagnosis and mostly is independent of renal function [12]. It is

usually normocytic and normochromic and related both to the replacement of normal marrow by expanding tumor cells and to the inhibition of hematopoiesis by factors secreted by the tumor.

The diagnosis of symptomatic MM requires the presence of clonal plasma cells on bone marrow examination or biopsy-proven plasmacytoma, monoclonal (M) protein in the serum and/or urine, and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or bone lesions) believed secondary to the underlying plasma cell disorder [17].

Conventional radiography shows skeletal abnormalities in approximately 80% of patients. With magnetic resonance imaging (MRI), it is possible to determine the extent of marrow infiltration in the axial skeleton despite having normal plain radiological examinations [18]. Positron emission tomography (PET) is now also being used in the evaluation of myeloma as it has improved sensitivity over skeletal X-rays. The M protein can be detected by serum protein electrophoresis in >80% of patients and by immunofixation in >90% [12,19]. Up to 20% of patients with MM are considered to have light-chain MM. The M protein in these patients is always detected in urine but can be absent in serum, even by immunofixation.

Table 55.1 New International Staging System for myeloma

Stage	Criteria	Median survival (months)
I	Serum β_2-microglobulin <3.5mg/L Serum albumin ≥3.5g/dL	62
II	Not stage I or III[a]	44
III	Serum β_2-microglobulin ≥5.5mg/L	29

[a] There are two categories for stage II: serum β_2-microglobulin <3.5mg/L but serum albumin <3.5g/dL, and serum β_2-microglobulin 3.5 to <5.5mg/L irrespective of serum albumin level.

Source: Rajkumar et al. 2010 [46]. Reproduced with permission of Elsevier.

Among patients with MM, 3% have no detectable M protein on serum or urine immunofixation and are considered to have non-secretory MM. In these patients, the serum free light chain (FLC) assay, which measures the level of free (unbound) kappa and lambda light chains in the serum, is helpful for diagnosing and monitoring response to therapy. The FLC kappa/lambda ratio is used to distinguish polyclonal elevations seen with renal dysfunction from monoclonal elevations that occur in clonal plasma cell disorders [20,21].

Staging, prognosis, and response

Median survival has traditionally been quoted as approximately 3 years. However, improvements in therapies and supportive care have dramatically improved the prognosis.[22]. Survival depends on both tumor burden and intrinsic biologic features. Tumor burden has traditionally been measured using the Durie–Salmon staging system. This staging system has limitations, especially in the categorization of bone lesions [23]. The more recent International Staging System (ISS), which was a collaborative effort by investigators from 17 institutions worldwide based on data from more than 11,000 patients, overcomes the limitations of the Durie–Salmon staging and divides patients into three distinct stages and prognostic groups on the basis of serum β_2-microglobulin and albumin levels (Table 55.1) [24]. Selected clonal chromosomal abnormalities have also emerged as adverse prognostic markers. These include hypodiploidy, deletions involving chromosomes 1, 13s and 17, and translocations involving IgH locus on chromosome 14 [25].

New uniform response criteria are required to assess clinical outcomes in myeloma adequately. Table 55.2 shows the European

Table 55.2 Definitions for response categories

Response subcategory	Response criteria[a]
CR	Negative immunofixation on the serum and urine and Disappearance of any soft tissue plasmacytomas and ≤5% plasma cells in bone marrow [b]
sCR	CR as defined above plus Normal FLC ratio and Absence of clonal cells in bone marrow [b] by immunohistochemistry or immunofluorescence [c]
VGPR	Serum and urine M-component detectable by immunofixation but not on electrophoresis or 90% or greater reduction in serum M-component plus urine M-component <100mg per 24 h
PR	≥50% reduction of serum M-protein and reduction in 24-h urinary M-protein by ≥90% or to <200mg per 24h If the serum and urine M-protein are unmeasurable [d], a ≥50% decrease in the difference between involved and uninvolved FLC levels is required in place of the M-protein criteria If serum and urine M-protein are unmeasurable, and serum free light assay is also unmeasurable, 50% reduction in plasma cells is required in place of M-protein, provided baseline bone marrow plasma cell percentage was 30% In addition to the above criteria, if present at baseline, a 50% reduction in the size of soft tissue plasmacytomas is also required
SD (not recommended for use as an indicator of response; stability of disease is best described by providing the time to progression estimates)	Not meeting criteria for CR, VGPR, PR, or progressive disease

CR, complete response; PR, partial response; sCR, stringent complete response; SD, stable disease; VGPR, very good partial response; FLC, free light chain.

[a] All response categories require two consecutive assessments made at any time before the institution of any new therapy; complete and PR and SD categories also require no known evidence of progressive or new bone lesions if radiographic studies were performed. Radiographic studies are not required to satisfy these response requirements.

[b] Confirmation with repeat bone marrow biopsy not needed.

[c] Presence/absence of clonal cells is based upon the k/λ ratio. An abnormal k/λ ratio by immunohistochemistry and/or immunofluorescence requires a minimum of 100 plasma cells for analysis. An abnormal ratio reflecting presence of an abnormal clone is k/λ of >4:1 or <1:2. Alternatively, the absence of clonal plasma cells can be defined based on the investigation of phenotypically aberrant plasma cells (PCs). The sensitivity level is 10^{-3} (less than one phenotypically aberrant PC within a total of 1000 PCs). Examples of aberrant phenotypes include (1) $CD38^{+dim}$ and $CD56^{+strong}$ and $CD19^{-}$ and $CD45^{-}$; (2) $CD38^{+dim}$ and $CD138^{+}$ and $CD56^{++}$ and $CD28^{+}$; (3) $CD138^{+}$, $CD19^{-}$ $CD56^{++}$, $CD117^{+}$.

[d] *Definitions of measurable disease*

Response criteria for all categories and subcategories of response except CR are applicable only to patients who have "measurable" disease defined by at least one of the following three measurements:

Serum M-protein ×1g/dL (×10gm/L) [10 g/L];

Urine M-protein ×200mg/24h;

Serum FLC assay: involved FLC level ×10mg/dL (×100mg/L) provided serum FLC ratio is abnormal.

Group for Blood and Marrow Transplantation/International Bone Marrow Transplant Registry (EBMT/IBMTR) criteria that have been expanded, clarified, and updated to provide an improved comprehensive evaluation system [26].

Myeloma therapy

Importance of achieving a complete response

Achievement of a complete remission as defined by the International Myeloma Working Group (IMWG) criteria has emerged as the single most important surrogate prognostic factor for survival [27]. A meta-analysis of 21 studies demonstrated that maximal response was associated with overall survival (OS) and event-free survival (EFS) benefit [28]. Likewise, Martinez-Lopez et al. demonstrated that outcomes were significantly better for patients achieving a CR compared with those who only achieved a very good partial remission (VGPR) or a near CR [29]. CR does not imply eradication of the malignant clone. Sensitive techniques such as flow cytometry and polymerase chain reaction (PCR) routinely show significant residual disease in patients achieving CR by IMWG criteria [30,31]. Reduction of tumor burden as documented by multiparameter flow cytometry has been shown to be an important prognostic factor for progression-free survival (PFS) (71 months vs. 37 months) among patients treated uniformly on the GEM2000 protocol [32,33]. CR duration is emerging as an important prognostic factor for survival. Hoering et al. reported that for patients with CR durations of more than 3 years the 10-year survival estimate was 54% versus 17% for patients losing their CR within 3 years and 35% for patients never achieving a CR [34].

Therapeutic approaches for SCT-eligible patients

Only patients with symptomatic myeloma require initiation of therapy. Once a decision has been made to initiate therapy, a decision should be made whether a patient is a potential candidate for an autologous SCT. Age by itself can no longer be considered a criterion for transplant eligibility since most centers can perform autologous SCT safely in patients in their 70s and 80s if physically fit and medically stable [35–39]. Therapy for myeloma is commonly divided into three phases: induction, consolidation, and maintenance. For transplant-eligible patients, it is important to avoid treatment with alkylating agents such as melphalan that are toxic to progenitor cells, and may interfere with adequate hematopoietic cell (HC) mobilization and collection [40–42].

Induction therapy

Goals of induction therapy in the transplant-eligible patient are based on evidence demonstrating an association between depth of response and PFS and, more importantly, OS. Prior to the advent of immunomodulatory drugs (IMIDs) and proteosome inhibitors, the superior survival seen with high-dose chemotherapy and autologous ASCT was related to the higher CR rates seen with high-dose therapy [43]. Depth of response prior to transplant, that is, after induction therapy, can improve PFS and possibly OS post-transplant [44]. However, it is not only the achievement of a CR but also the duration of CR that is important in long-term survival. Patients with high-risk disease, classically defined by cytogenetics, can achieve rapid responses with modern chemotherapy regimens, but these remissions are often short lived [34]. Hence the heterogeneity of myeloma underscores the challenges of treatment decisions for induction, transplant, and post-transplant therapy.

The combinations of vincristine, adriamycin, and dexamethasone (VAD) or thalidomide and dexamethasone were considered for many years the gold standards for induction therapy for transplant-eligible patients [45]. Lenalidomide has a more favorable toxicity profile than thalidomide, which made it a more attractive induction choice. The ECOG trial of lenalidomide plus high-dose dexamethasone versus lenalidomide plus low-dose dexamethasone (40mg weekly) confirmed the safety and low toxicity of both the choice of lenalidomide as induction and the improved safety profile of lowering the dexamethasone dose [46]. One-year survival was over 90% in both older and younger patients in the low-dose dexamethasone arm. This led to a major paradigm shift in the United States with regard to both the dexamethasone dose and s the use of lenalidomide upfront preferentially over thalidomide.

For certain subgroups of patients such as those with renal insufficiency or specific cytogenetic abnormalities such as t(4;14), bortezomib-based induction may be a more favorable option. Several large randomized trials have studied bortezomib-based induction compared with traditional regimens. The IFM 2005 trial compared bortezomib plus dexamethasone with VAD followed by autologous SCT. The primary trial end-point was complete/near complete response (nCR) rate. The bortezomib arm had a CR/nCR rate of 14.8% compared with 6.7% in the VAD arm. There was also a non-significant trend towards a longer PFS in the bortezomib arm [47]. Analysis of patients with t(4;14) by retrospective comparison of bortezomib plus dexamethasone-treated patients including those from the IFM 2005 trial compared with a similar group induced with VAD showed a superior EFS of 28 months for the bortezomib-treated patients compared with 16 months for VAD-treated patients [48].

Three-drug combinations are also an induction choice for patients. The most common regimens are VTD (Velcade/bortezomib–thalidomide–dexamethasone), RVD (Revlimid/lenalidomide–Velcade/bortezomib–dexamethasone), and CyBord (cyclophosphamide–bortezomib–dexamethasone). Of these, only VTD has phase III results in comparison with a two-drug combination. A study of VTD versus TD (thalidomide–dexamethasone) as induction and consolidation post-autologous ASCT showed a better response rate and PFS with the three-drug arm but no overall survival advantage [49]. The recently completed SWOG S0777 trial of lenalidomide plus low-dose dexamethasone versus RVD will also provide further evidence either for or against a three-drug regimen. The Evolution trial, a randomized phase II trial of RVD versus VCD (Velcade/bortezomib–cyclophosphamide–dexamethasone) versus VDCR (Velcade/bortezomib–dexamethasone–cyclophosphamide–Revlimid/lenalidomide) showed comparable VGPR/CR rates and 1-year PFS for the VCD and RVD arms and the VDCR arm [50].

In addition to efficacy, toxicity must also remain a consideration when choosing a regimen, This applies to patient comorbidities present at the start of induction and also the potential for long-term toxicity. For example, bortezomib can produce severe peripheral neuropathy. This risk is greater in patients with underlying neuropathy such as diabetics, and also in older patients. Hence the choice of a bortezomib-based induction must weigh this risk in addition to consideration of myeloma-related factors such as cytogenetics The use of alternative bortezomib schedules such as weekly dosing and alternative routes such as subcutaneous administration have also been shown to reduce the incidence of neuropathy. Hence this provides further options to patients at risk for neuropathy [51–53]. One advantage of bortezomib is that it does not require dose reduction in the setting of renal insufficiency, which makes it an attractive choice for renally impaired patients. In addition, there is no concern about stem-cell yields with long-term bortezomib use.

IMIDs, on the other hand, offer the advantage of an oral regimen. In the case of lenalidomide, the incidence of neurotoxicity is low. The ECOG E4A03 trial underscores the high tolerability and excellent long-term survival of lenalidomide upfront when combined with low-dose dexamethasone. However, because of the thrombotic risk of IMIDs, all patients require antithrombotic prophylaxis – this is generally with aspirin in low-risk patients, but in patients at high risk for thrombosis either low molecular weight heparin or full-dose warfarin is required [54]. The other concern with lenalidomide in particular is its effect on stem-cell yields. Retrospective studies have raised the concern of impaired stem-cell collection from patients who have been on long term lenalidomide. This may be overcome to some extent by using either chemotherapy mobilization or plerixafor, a receptor chemokine receptor 4 (CXCR4) inhibitor. This led to the IMWG consensus recommendations that stem cells be collected with cyclophosphamide plus granulocyte colony-stimulating factor (G-CSF) for patients with over 4 months or more of lenalidomide exposure, and for patients over 65 years of age cyclophosphamide or plerixafor plus G-CSF-based priming should be considered [42].

In general, patients are treated with three or four cycles of an induction regimen before proceeding to transplant. The optimal number of cycles prior to transplantation is unknown. Although all of the aforementioned regimens have high response rates, the depth of response deepens with continued therapy [55]. For example in the phaseI/II trial of RVD, the quality of response continued to improve between cycles 4 and 8 [56]. Although it would theoretically be ideal to achieve a minimal residual disease state prior to stem-cell transplantation, the implications of delaying SCT until a plateau have never been studied. With the advent of more potent induction regimens, this may be less of a controversy. Jakubowiak et al. recently reported that the combination of a new proteasome inhibitor, carfilzomib, together with lenalidomide and dexamethasone resulted in an nCR rate of 62% with a stringent CR rate of 42%, with major responses achieved within 6 months of initiation of therapy [57]. In summary, induction therapy with a combination of an IMID and a proteosome inhibitor has become the standard of care for myeloma patients, replacing thalidomide and dexametahsone and also VAD.

Autologous stem-cell transplantation for myeloma

High-dose melphalan without autologous hematopoietic cell transplantation (HCT) was first reported in 1983 by McElwain et al. at the Royal Marsden Hospital [58]. Patients received 100–140mg/m^2 of melphalan, and three previously untreated patients achieved a CR. High-dose therapy with autologous HCT to reduce the regimen-related toxicity was first reported by Barlogie et al. in 1986 [59]. They used up to 140mg/m^2 of melphalan intravenously. Over the next 25 years, high-dose therapy and autologous HCT evolved into a safe and common therapeutic approach for patients with MM. Compared with chemotherapy alone, intensified chemotherapy followed by autologous HCT has been shown to prolong both EFS and OS in previously untreated patients with myeloma. Various randomized trials and non-randomized analyses have shown both survival and PFS benefits in favor of autologous HCT of approximately 12 months (reviewed in [60,61]). All of these studies are now considered historical since none of them included modern induction therapy with a proteosome inhibitor and an IMID [35,62]. Hence the role of high-dose therapy with autologous SCT as consolidation for all patients with myeloma needs to be re-explored. Three randomized trials are looking at this question and their results are eagerly awaited [55].

Preparative regimens

Many different preparative regimens have been assessed over the last 25 years. Only one prospective, randomized trial by a French Cooperative group has directly compared two different preparative regimens. In 282 newly diagnosed symptomatic patients <65 years of age, they reported that high-dose melphalan at 200mg/m^2 is superior to a combination of melphalan 140mg/m^2 + 8Gy of total body irradiation (TBI) mainly by reducing toxicity including mucositis and transplant-related mortality (TRM) [63]. Melphalan 200mg/m^2 was associated with a faster hematologic recovery, reduced transfusion requirements, and a shorter hospitalization. Although the median duration of EFS was similar in both arms (21 months), survival at 45 months was significantly better in the melphalan-alone arm (66% vs. 46%, $p = 0.05$). As a result, melphalan 200mg/m^2 is the standard conditioning regimen used for autologous HCT in myeloma, with dose reductions based on age and renal function. In two non-randomized studies and a registry analysis, use of more intensive preparative regimens, such as busulfan with melphalan [64], thioTEPA (*N*-triethylenethiophosphoramide), busulfan, and cyclophosphamide [65] or high-dose idarubicin, cyclophosphamide, and melphalan [66] did not result in better outcomes than melphalan at a dose of 200mg/m^2. Recently, Blanes et al. compared SCT outcomes for 51 newly diagnosed patients with MM who received intravenous busulfan in combination with melphalan with the outcomes for 102 patients receiving melphalan 200mg/m^2 in a 1:2 matched control analysis. After a median follow-up of 63 and 50 months in control and IV busulfan, the median PFS was 24 and 33 months ,respectively [67]. Other recent work has focused on combining proteasome inhibitors with melphalan. Lonial's group demonstrated that the combination was feasible – in a group of 39 patients the response rate was 87% with 51% achieving a VGPR or greater [68]. In addition, pharmacodynamic studies demonstrated that sequencing of the drug may be important with greater plasma cell apoptosis seen in patients who received bortezomib after the high dose melphalan.

Relapse after autologous HCT remains the single most important cause of treatment failure in patients. Strategies aimed at improving the conditioning regimen have usually focused on intensifying the conditioning regimen either by increasing the dose of melphalan or by adding other alkylating agents, as summarized in Table 55.3. Of these, only tandem high-dose therapy has been reported to improve outcomes in randomized trials [69–72]. This benefit is limited because many patients do not want to undergo tandem transplantation, and it is possible that only patients failing to achieve a greater than 90% reduction of their myeloma burden after the first high-dose therapy benefit from a second intensification.

Various groups have explored dose intensification of melphalan with or without cytoprotectors such as amifostine. Phillips et al. demonstrated the feasibility of administering up to 280mg/m^2 of melphalan with amifostine. Significant mucosal toxicities were observed, and at the higher doses cardiotoxicity was dose limiting [73]. Moreau et al. explored the use of melphalan at a dose of 220mg/m^2 as part of a tandem transplantation strategy for patients with high-risk myeloma as defined by cytogenetics and β_2-microglobulin. CRs were seen in 30% of patients, with a further 18% achieving at least a 90% reduction in tumor burden [74]. To date, neither melphalan dose intensification nor the addition of

other alkylating agents has resulted in large increases in post-transplantation CR rates, and novel conditioning regimens exploring different mechanisms of enhancing the antitumor effect of high-dose melphalan need to be further explored.

It is now well established that the interactions between malignant plasma cells and the bone marrow microenvironment that includes stromal cells, extracellular adhesion molecules, and secreted cytokines are important contributors to myeloma resistance and disease recurrence [11]. Novel therapies targeting these interactions have shown promising responses and outcomes. Bortezomib [68,75,76] and targeted skeletal radiotherapy with either holmium DOTMP (1,4,7,10-tetraazcyclododecane-1,4,7,10-tetramethylenephosphonate) or samarium EDTMP [ethylenediaminetetra(methylenephosphonic acid)] [77,78] have been studied as part of the conditioning regimen, with encouraging phase II results that need to be confirmed in larger phase III trials. Of these, bortezomib–melphalan combinations are being intensely explored. Roussel et al. reported on 54 patients who received bortezomib 1mg/m^2 on days –6, –3, +1, and +4 in addition to melphalan 200mg/m^2. VGPR and CR rates were 70% and 32%, respectively, with no increases in toxicity. Compared with a matched control group treated with high-dose melphalan alone, the CR rates were higher (35% vs. 11%) [76]. Lonial et al. performed a randomized phase I/II trial among patients who failed to achieve a VGPR after one or more induction regimens. Of the 39 patients randomized, 20 received bortezomib after melphalan and 19 received bortezomib before melphalan. The overall response rate for all patients was 87%, with 51% achieving a VGPR or better. Pharmacodynamic studies showed greater plasma cell apoptosis among patients who received bortezomib following melphalan [68]. Taken together, these studies demonstrate that adding bortezomib to high-dose melphalan is feasible but that randomized trials will be needed to demonstrate whether the combination is better than melphalan alone.

The tolerance to high-dose melphalan is extremely heterogeneous, with some patients exhibiting no symptoms whereas others are affected by serious life-threatening toxicities. Even without severe toxicities, patient-reported outcomes vary significantly, as found by the M.D. Anderson group [79]. To a certain extent, this variability is probably due to genetic polymorphisms among enzymes such as glutathione-*S*-transferase [80]. However, the practice of dosing melphalan according to body surface area, with arbitrary modifications for overweight patients, also suggests that melphalan dosing may be implicated, as reported by Grazziutti et al. [81]. Nath et al. reported that current dosing results in a 4.3-fold variation in exposure, with AUC$_{0-\infty}$ values ranging from 5.8 to 24.7mg/L/h (median: 12.7mg/L/h). This variation probably impacts toxicity and myeloma responses [82].

Lastly, Dimopoulos et al. demonstrated that the extent of damage and repair seen in the *p53* tumor suppressor gene of peripheral blood lymphocytes after exposure to melphalan is an important predictor of outcome, and could serve as a tool for developing a personalized or individually tailored conditioning regimen [83].

Patient selection

Older age

Most centers excluded patients over the age of 70 years, because of the potentially greater risk of regimen-related toxicities. However, advances in supportive care have made autologous HCT feasible in older patients. In a study of patients undergoing tandem autologous HCT, 49 patients aged 65 years or older were compared with 49 pair-mates matched for prognostically relevant disease drawn from 501 younger patients, CR duration, EFS, and OS were comparable in the two groups [36]. The prognosis was primarily determined by presence of unfavorable cytogenetics (11q breakpoints, monosomy 13 or deletion 13q, or any translocation), and serum β_2-microglobulin level of over 2.5mg/L. The authors concluded that age should not constitute a criterion for exclusion from high-dose regimens. Similar results were obtained in three other retrospective analyses, including a large registry analysis from the CIBMTR [37–39].

Renal failure

Although renal failure increases the morbidity and mortality of myeloma, at least two reports have shown that high-dose therapy and autologous HCT are feasible in patients with concurrent myeloma and renal failure. Renal failure apparently has no adverse effect on either the quality of hematopoietic cell (HC) collection or engraftment following autologous HCT, and the toxicity is acceptable, with survival comparable to that of other patients [84,85]. In a study of patients with MM and a serum creatinine level over 2.0 mg/dL undergoing autologous HCT, the median OS for the entire group of 81 patients was longer than 53 months, and was more than 51 months for the 38 patients who were dialysis dependent. In this study, only two dialysis patients recovered partial renal function post-transplantation [84]. In a second study, four of 17 evaluable patients became independent of dialysis at a median time of 5 months post-transplantation [85]. Patients on dialysis undergoing autologous SCT should be considered for a lower dose of melphalan (usually 140mg/m^2) owing to increased risk of serious adverse events with 200mg/m^2 in this population.

Stem-cell source

Peripheral blood hematopoietic cells (PBHCs) are preferred over bone marrow cells for transplantation because of rapid and predictable engraftment, and possibly less contamination of the graft with tumor cells [61]. The absolute number of CD34$^+$ cells/kg recipient weight is the most reliable and reproducible method for determining the dose of the HC product. PBHCs should be collected before the patient is exposed to alkylating agents. The current practice at many transplant centers is to harvest enough HCs for two transplantations; a single transplantation is performed with half of the collected cells, and the other half is cryopreserved. The minimum recommended CD34$^+$ dose to support one autograft is 2×10^6 CD34$^+$ cells/kg recipient weight; patients receiving 5×10^6 CD34/kg or more have more rapid platelet recovery [86]. Although retrospective analysis has shown that the risk of relapse is lower for recipients of syngeneic transplants than for autograft recipients, randomized trials of CD34 selection of autografts as a strategy for purging failed to show improved outcomes [87–90].

Current role of autologous HCT in myeloma

Since 1995, more than a dozen randomized trials have been performed addressing transplant-specific issues in myeloma. The most representative of these trials are summarized in Table 55.3. The first generation of randomized trials started with the IFM 90 trial. In this trial, high-dose chemotherapy supported by autologous bone marrow transplantation (BMT) was compared with conventional chemotherapy in 200 previously untreated patients less than 65 years of age with myeloma [91]. The results showed a higher CR rate (22% vs. 5%), a higher rate of 5-year EFS (28% vs. 10%), and greater OS (52% vs. 12%) in the autologous BMT group. There was a 13 months' longer median duration of OS in patients assigned to the BMT arm (57 months vs. 44 months) and improved median EFS (from 18 to 27 months). Soon afterwards, the the Medical Research Council Myeloma VII trial randomized 401 previously untreated patients less than 65 years of age with myeloma, with similar outcomes to the IFM 90 trial. CR rates were higher in the autologous HCT group (44% vs. 8%; 19 months vs. 31 months) [92]. Three other randomized studies, however, have not shown a survival benefit of autologous HCT. Comparison between these trials is difficult owing to variability in patient eligibility, including age, induction chemotherapy, the conditioning regimen for the HCT, and definitions of response [93–95].

Barlogie and co-workers were the first to report on the potential role of tandem SCT in the late 1990s. Among 231 patients with newly diagnosed MM who received tandem autologous HCT, second transplantations were performed in 71%. After the first autologous HCT, 41% achieved CR and 83% achieved CR or partial remission (PR). These numbers were increased to 51% CR and 95% CR or PR in patients completing a second transplantation. Median duration of remission in complete responders was 50 months. In an updated analysis, 15-year OS and disease-free survival (DFS) were 17 and 7%, respectively, and having received a tandem SCT was an important variable for survival in multivariate analysis [96,97]. Based on these results, the next generation of randomized trials explored the role of tandem versus single high-dose therapy as consolidation for upfront myeloma therapy. The IFM 95 trial randomized 399 previously untreated patients to a single versus a tandem SCT strategy. Long-term outcomes demonstrated a significantly improved 7-year EFS (20% vs. 10%) and OS (42% vs. 21%) in recipients of double versus single autologous HCT [98,99]. Cavo et al. reported on 321 patients randomly assigned to receive either a single course of high-dose melphalan at 200mg/m^2 or melphalan at 200mg/m^2 followed, after 3–6 months, by melphalan at 120mg/m^2 and busulfan at 12mg/kg [100]. Patients in the tandem autologous HCT arm had a significantly increased probability of attaining at least an nCR (33% vs. 47%, respectively; $p = 0.008$), prolonged relapse-free survival (median 24 versus 42 months, respectively; $p < 0.001$), and prolonged EFS (median 23 vs. 35 months, respectively; $p = 0.001$). OS, however, was not prolonged in this study, possibly because 50% of patients randomly assigned to receive a single autologous HCT received an autologous SCT as salvage and the appearance of novel agents such as bortezomib and thalidomide [100]. Thus, by 2005, high-dose melphalan with autologous SCT had emerged as the most effective strategy to obtain CRs in myeloma and was considered an established standard of care compared with the conventional chemotherapy regimens of the time [61]. However, with modern induction regimens resulting in CR rates of 30% or greater, the role of upfront high-dose therapy for all patients with myeloma is currently being readdressed through various large randomized trials [55,101,102].

The emerging role of maintenance therapy post-SCT

Improvements in induction therapy have led to higher response rates, and also improved PFS post autologous stem-cell transplantation. However, the majority of patients with myeloma will relapse post-SCT. Strategies to improve relapse include consolidation therapy and maintenance therapy. The definitionsof and line between consolidation and maintenance can be rather blurred. Generally, consolidation is thought of as a finite course of therapy administered relatively early post-transplant with the aim of deepening the response achieved with the transplant ideally to a minimal residual disease state. Maintenance is usually a less intense therapy but administered for longer periods, often in fact until disease progression. Early maintenance trials used interferon, with mixed results. It was poorly tolerated and on meta-analysis led to an approximately 6-month improvement in long-term survival [103]. The IFM 99-02 study randomized patients after tandem autologous transplant to thalidomide plus pamidronate, pamidronate alone, or observation [104]. An improvement in EFS and OS was seen in the thalidomide arm; however, this benefit was restricted to those with less than a VGPR post-transplant, without deletion 13 or high β_2-microglobulin. Barlogie and co-workers demonstrated that the impact of thalidomide maintenance may not be seen early on but only after long-term follow up [105,106]. The MRCIX trial demonstrated a significant PFS but not OS benefit to thalidomide maintenance [107]. The HOVON 50 study randomized patients from induction to a thalidomide arm and a thalidomide, adriamycin, and dexamethasone (TAD) versus VAD arm. Both arms then underwent single or tandem autologous transplant. The TAD arm went on to receive thalidomide maintenance and the VAD arm interferon maintenance. The TAD arm had a longer EFS (33 months vs. 22 months) and a non-significant trend to improved OS (62 months vs. 59 months). However, since thalidomide was included as part of induction, it is difficult to sort out what benefit this played in PFS post-transplant versus the maintenance thalidomide [108].

A meta analysis by the IMWG corroborated the finding of a significant reduction in risk of progression in patients on thalidomide maintenance [110]. However, the analysis revealed variability with regard to an vOS benefit (test for heterogeneity 0.03), although with a positive effect. The trialists explanation for this variability included the facts that elderly patients were part of two trials and the variability of the availability of novel agents at relapse depended on the country. It is clear from all trials that long-term thalidomide use is difficult owing to its toxicity profile, especially the cumulative peripheral neuropathy. Nonetheless, in certain countries where other novel agents are not available in the maintenance setting, the use of thalidomide maintenance in patients without deletion 13 can be considered. The optimal duration of use remains unknown. There was wide variability in the duration of thalidomide use in the many trials, in part due to patient tolerance of the drug. In the IFM 99-02 trial, the median duration of therapy was 15 months versus 7 months in the MRCIX trial.

Lenalidomide, with its more favorable side-effect profile, is a more attractive choice for maintenance. Two randomized trials have been completed, evaluating the benefit of lenalidomide post-autologous transplant versus observation. In the IFM 2005-01 trial, all patients received two cycles of lenalidomide consolidation at a dose of 25mg/day for 21 days, and subsequently they were placed on either placebo or lenalidomide until disease progression. Interim analysis demonstrated a significant benefit to the lenalidomide arm and the study was therefore unblinded, and no crossover from placebo was allowed [111]. There was a significant upgrading of response, with CR rates increasing from 14 to 20% in the lenalidomide arm ($p < 0.001$). PFS was 41 months in the lenalidomide arm and 23 months in the placebo arm ($p < 0.001$). This benefit was seen independent of response at randomization or β_2-microglobulin at study entry. In patients with poor risk cytogenetics, PFS and OS were shorter than in standard risk patients, even in the lenalidomide arm. So far there has been no demonstrable overall survival benefit. The 4-year estimated OS was 79% in the lenalidomide arm versus 73% in the placebo arm.

The CALGB 100104 trial also evaluated lenalidomide maintenance versus observation. There was no consolidation phase in this trial and patients were placed on lenalidomide from 10mg up to 15mg daily versus placebo post-transplant until disease progression. This trial also at interim analysis demonstrated a significant PFS benefit to the lenalidomide arm, and it was unblinded early. PFS was 46 months in the lenalidomide arm versus 27 months in the placebo group. In contrast to the French trial, patients in the placebo arm were allowed to cross over to lenalidomide. Even with this crossover, at a median follow-up of 34 months there was an overall survival advantage in the lenalidomide arm [112]. In the CALGB trial, lenalidomide maintenance was effective in patients with either high or low β_2-microglobulin levels and regardless of prior exposure to thalidomide or lenalidomide. The two studies demonstrated that lenalidomide was overall well tolerated, with only about 20% of patients in the lenalidomide arms coming off therapy because of adverse events. Both studies are too immature to assess if there is a shorter survival post-relapse in the lenalidomide-treated patients, and since the CALGB trial allowed a crossover for placebo patients, it may not be possible to assess this (Figure 55.1). Both trials demonstrated that lenalidomide maintenance was associated with higher rates of second cancers, both solid tumors and hematologic malignancies. The CALGB trial reported an 8% incidence versus 2% in the placebo arm, and the IFM trial 3.1 per 100 patient years versus 1.2 per 100 patient years in the placebo group. The reason for this increased risk is unclear. Multivariate analysis in the French trial identified age >55 years, male gender, DCEP (dexamethasone, cyclophosphamide, etoposide, and cisplatin) induction, and ISSIII as risk factors for development of a second primary cancer. Because of this finding, no firm recommendation was made by the IMWG group in their consensus statement on maintenance therapy [110–112]. In general, the risk of maintenance with regard to side effects, quality of life, and especially second malignancies must be weighed against the risk of myeloma disease progression.

Bortezomib maintenance post=transplantation has proven to be more challenging to explore owing to the parenteral route of administration and the high incidence of neuropathy with long-term use. However, its potential benefits as part of induction therapy, as seen in the IFM trials, in specific high risk cytogenetic subgroups (t4;14), make it an agent worthy of further study [113] Two trials, the HOVON 65 MM/GMMG-HD4 trial and the PETHEMA/GEM VTD vs TD trial, have used it post-transplant. However, the data with regard to the degree of benefit are difficult to evaluate, as bortezomib was also included in the induction. For example, the HOVON trial randomized patients to PAD (bortezomib, adriamycin, and dexamethasone) versus VAD [114] The VAD arm post-transplant received thalidomide maintenance and the PAD arm received bortezomib maintenance for 2 years. Patients with 17p deletion, a known poor-risk group, benefited the most from bortezomib treatment with a median PFS of 26.2 months versus 12 months in the VAD/thalidomide arm. Interestingly, only a marginal benefit was seen in t(4;14) patients (25.3 months vs. 21.7 months),

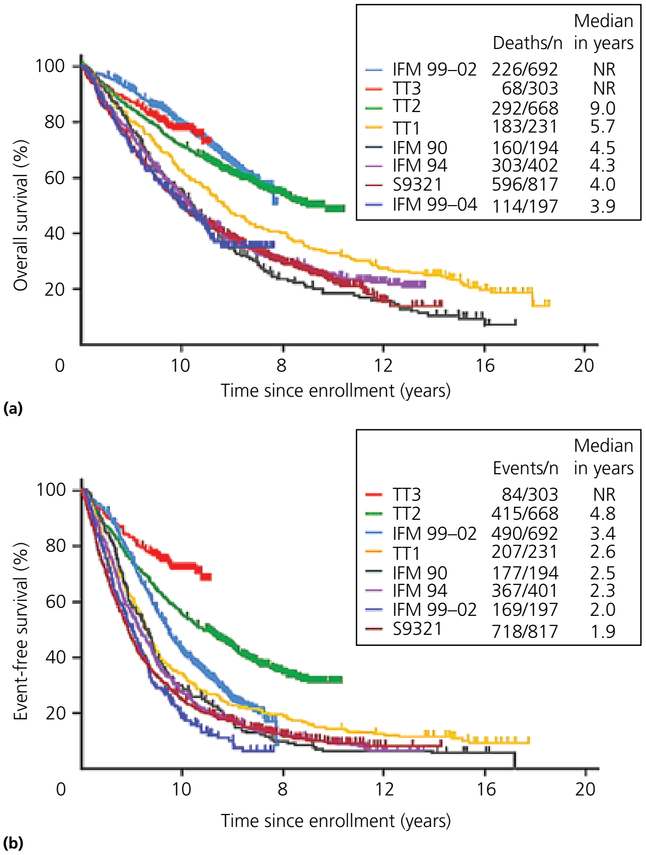

Figure 55.1 Long-term outcomes of large prospective autologous SCT trials. Source: Barlogie et al. 2010 [106]. Reproduced with permission of the American Society of Clinical Oncology. (For a color version of this figure, please see the color plate section.)

although the authors surmised that this was because chromosomal aberrations were analyzed in conjunction with ISS score, which may have diluted out the effects of t(4;14). However, since bortezomib was also given as induction but only in one arm, it remains unclear what influence this had on long-term outcome versus the maintenance portion. Also, the toxicity profile of bortezomib was an issue; 27% of patients required dose reductions and 47% went off bortezomib maintenance, with 9% discontinued due to bortezomib-related toxicity, with peripheral neuropathy predominating [115].

The PETHEMA/GEM trial randomized patients to induction with TD versus VTD versus VBMCP/VBAD/bortezomib, where VBMCP = vincristine, BCNU [1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine)], melphalan, cyclophosphamide, and prednisone and VBAD = vincristine, BCNU, doxorubicin, and dexamethasone. The complete remission rate in the poor-risk cytogenetic groups was significantly higher in the VTD arm than the TD or VBMCP/VBAD arms. The maintenance portion consisted of thalidomide plus bortezomib (TV) versus thalidomide (T) versus α_2-IFN with a planned duration of maintenance of 3 years or until disease progression in all arms. At a median follow-up of 24 months, the PFS was significantly longer in the TV arm (78% vs. 63% T vs. 49% VBMCP), but OS was not different between the three arms. Interestingly, the discontinuation rate was significantly higher in the T arm than the TV arm (30% vs. 15.6%). So far there are no data on PFS in the high-risk subgroups. In addition, given the different induction regimens, it again begs the question of the role of bortezomib in induction versus maintenance [116,117]. The use of alternative routes of bortezomib administration such as subcutaneous dosing and weekly dosing have been shown to reduce rates of peripheral neuropathy. Notwithstanding, the long-term impact of these new schedules or routes of administration has not been well studied in the maintenance setting [118–120].

Role of consolidation post-SCT

Prior to the advent of novel agents, the approach to consolidation was tandem transplantation, with the second transplant consolidating response from the first, especially in patients with less than a VGPR to the first [96–100]. With the advent of novel agents, another approach has been to supplant the second transplant with treatment with either single agents or combination therapy in the early post-transplant period. Ladetto et al. demonstrated the feasibility and potential benefit of this approach [121]. They enrolled 39 patients who had achieved at least a VGPR post-transplant and who had an available molecular marker based on IgH rearrangement. They ultimately treated 31 patients with four courses of VTD in combination. The response to therapy was assessed with qualitative and quantitative PCR using tumor-specific primers. Traditional response criteria were also used. By these criteria, the CR rate increased from 15 to 49%. The molecular remission rate also increased from 3% post-transplant to 18% post-VTD. With a median follow-up of 42 months at the time of reporting, no patient in molecular remission had relapsed.

Single-agent bortezomib was used as consolidation in the Nordic Myeloma Group phase III trial [122]. In this large trial of 392 patients, there was a randomization post-transplant to no treatment or bortezomib for two 3-week cycles of a traditional day 1, 4, 8, 11 schedule and then four 4-week cycles of a day 1, 8, 15 schedule. The planned total number of bortezomib injections was 20. The median number delivered was 19, suggesting that it was feasible and well tolerated. The incidence of grade III/IV peripheral neuropathy was only 3%. There was an upgrading of response with a CR/nCR rate of 54% in the bortezomib arm versus 35% in the observation arm ($p < 0.005$). However, no data have yet been reported regarding PFS, OS, or MRD.

The largest trial reported to date analyzing the role of consolidation therapy with IMiDs and proteasome inhibitor has been the GIMENA trial, reported by Cavo and co-workers [49,123]. In the original report, 480 patients were randomly assigned to receive VTD ($n = 241$ patients) or TD ($n = 239$). After induction therapy, CR or nCR was achieved in 31% of patients receiving VTD and 11% receiving TD ($p < 0{\cdot}0001$). The 3-year PFS was significantly longer in patients receiving VTD than in those on TD (68% vs. 56%), with similar 3-year OS rates (86% vs. 84%) [49]. In a follow-up report of patients who received treatment per protocol, the outcomes for the 160 patients who received VTD were significantly better than for those who received TD consolidation with respect to CR rate (60.6% vs. 46.6%). With a median follow-up of 30.4 months, the 3-year PFS was also superior for patients receiving VTD, 60% versus 48% for autologous SCT for newly diagnosed myeloma patients [intent-to-treat (ITT) analysis; VTD, $n = 236$; TD, $n = 238$]. This per-protocol analysis (VTD, $n = 160$; TD, $n = 161$) specifically assessed the efficacy and safety of consolidation with VTD or TD. After consolidation, CR rates were significantly higher in the VTD arm (60.6% vs. 46.6%). With a median follow-up of 30.4 months from start of consolidation, 3-year PFS was significantly longer for the VTD group (60% vs. 48% for TD) [123].

The US BMT CTN 0702 trial will evaluate this concept in a prospective randomized fashion. In this three-armed trial, patients will be randomized to single transplant, tandem transplant, or single transplant plus RVD consolidation for four cycles. All arms will receive lenalidomide maintenance. The primary study end-point will by 3-year PFS, but the trial will also assess depth of remission including MRD analysis in each study arm [55].

Autologous SCT as salvage therapy

In contrast to the upfront setting in which the role of high-dose therapy as consolidation of a first remission is well established, the utility of a second course of high-dose therapy with autologous SCT has not been established. Although multiple retrospective series have been published and are summarized in Table 55.4, no prospective trials have been performed to date, but retrospective results suggest that this may be a reasonable consolidation strategy for patients who have a long initial remission from their first high-dose regimen [124–131].

Future directions for autologous HCT in myeloma

MM is currently the most common indication for high-dose therapy with autologous HCT in North America and Europe [132]. Despite the high response rates for IMIDs and proteosome inhibitor combinations, many patients and physicians opt for high-dose therapy as consolidation of an initial remission and until the results of the large randomized trials comparing early with delayed SCT in the context of modern induction therapy are known this strategy should continue to be considered the standard of care. High-dose melphalan is used in over 90% of patients, with the most common regimen used being single-agent melphalan at a median dose of 180–200mg/m^2 performed as a single transplantation (CIBMTR, unpublished observations). Notwithstanding, patients with high-risk disease still have a remission duration of less than 3 years after autografting with most patients dying from their disease. Hence novel post-remission strategies need to be continuously explored, and likewise identification of patients who may have long-term disease control without upfront SCT could reduce the burden of treatment in a significant proportion of patients.

Allogeneic HCT in myeloma

The existence of a graft-versus-myeloma effect was first documented by Tricot et al., and later confirmed in large single- and multi-institutional series of donor lymphocyte infusion [133–136]. Thus, with the potential benefits of a graft-versus-tumor effect and the use of a clean HC product, it would be expected that high-dose therapy with allogeneic HCT would be extremely useful in the treatment of MM. Unfortunately, that is not necessarily the case. The EBMT case-controlled series reported that the relapse rate after allogeneic HCT was not significantly lower than the relapse rate after syngeneic HCT, suggesting that the graft-versus-tumor effect is not as potent in myeloma as it is in chronic or acute myelogenous leukemia [87].

A large report from the EBMT registry showed disappointing results for patients undergoing allogeneic HCT. Median survival was only 18 months, and the TRM was prohibitive at 41%. TRM, however, has been substantially reduced over the last decade even in the context of high-dose conditioning regimens [137]. To try to overcome toxicity from high-dose regimens, and to extend the applicability of allografting to older patients with significant comorbidities, allogeneic HCT after reduced-intensity conditioning (RIC) regimens has been attempted in patients with MM. Several phase II non-randomized trials and also large registry trials have been published and reported (reviewed in [138]). Various prospective donor versus no-donor biologic assignment studies have been performed and published comparing allogeneic SC consolidation with either autologous SCT or other alternative therapies. These trials are summarized in Table 55.5.

Garban et al. published the first of these prospective trials in patients with high-risk disease as defined by high levels of β_2-microglobulin or deletion of chromosome 13 as detected by FISH [139]. Patients received an initial autologous HCT with melphalan 200mg/m^2. Sixty-five patients had an HLA-identical sibling donor, of whom 46 patients received an RIC regimen consisting of fludarabine, busulfan, and antithymocyte globulin (ATG). Patients without an HLA sibling donor received a second autologous HCT prepared with melphalan 220mg/m^2. On an ITT basis, the OS and EFS did

[a] Median.

not differ significantly in both groups (median 35 and 25 months in the allogeneic HCT patients versus 41 and 30 months in the autologous HCT patients, respectively). There was a trend for a better OS in patients treated with tandem autologous HCT, with a median of 47.2 versus 35 months ($p = 0.07$) for patients who actually received a reduced-intensity allogeneic HCT.

The Italian Cooperative Group performed a similar study, which was reported by Bruno et al. [140]. After a median follow-up of 3 years, non-relapse mortality (NRM) was 11% for the autologous + allogeneic group versus 4% for the tandem autologous group ($p = 0.09$). CR was significantly higher in the autologous + allogeneic group than the tandem autologous group (6% vs. 16%, $p = 0.0001$). OS and EFS rates were superior in the autologous + allogeneic group to those in the tandem autologous group (84% vs. 62%, $p = 0.003$, and 75% vs. 41%, $p = 0.00008$, respectively). The results have held over time with subsequent follow-up reports [141]. Positive outcomes for recipients of allogeneic SCT were also reported by Björkstrand et al. [142]. A total of 357 patients participated in this EBMT prospective trial. Similarly to other designs, patients with an HLA-identical sibling donor were allocated to the auto-allo arm ($n = 108$) and patients without a matched sibling donor were allocated to the auto arm ($n = 249$). PFS at 60 months was 35% for the auto-allo arm versus 18% for the auto-auto arm; survival rates were similar in both arms with significantly higher relapse rates for the tandem auto arm (78% vs. 49%) but higher NRM rates for the auto-allo arm (12% vs. 3%).

These results contrast with those of HOVON 50 and more recently those of the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) Trial 0102. Lokhorst et al. reported on the donor versus no-donor analysis performed on patients treated in the HOVON 50 study. With a median follow-up of 77 months, no significant difference with regard to PFS was seen among the 138 patients without an HLA-identical sibling donor and 122 patients with a donor (6-year PFS 28% for donor, 22% for no donor). As with other studies, NRM was significantly higher in the donor arm (16% vs. 3%) [143]. Krishnan et al. reported on the transplant outcomes of 625 patients with standard-risk disease who received either an autologous hematopoietic stem-cell transplant (HSCT) ($n = 366$) or an allogeneic SCT ($n = 189$). Kaplan–Meier estimates of 3-year PFS were 43% in the auto-allo group and 46% in the tandem auto group; overall survival also did not differ at 3 years (77% vs. 80%) [144].

Hence the preponderance of data suggests that RIC allogeneic SCT after autologous HSCT is not more effective than tandem autologous HSCT for patients with standard-risk multiple myeloma. Further enhancement of the graft-versus-myeloma effect and reduction in TRM are needed to improve the allogeneic HSCT approach. Selecting patients who are more likely to benefit from a graft-versus-myeloma effect may improve the risk–benefit ratio for allografitng. Rosiñol et al. reported on SCT outcomes among 110 patients who had failed to achieve at least an nCR after a first autologous SCT who received either an RIC allograft ($n = 25$) or a second autograft SCT ($n = 85$) depending on the availability of an HLA-identical sibling donor. The CR rate was higher amongst the patients who underwent an allograft (40% vs. 11%, $p = 0.001$) and a trend towards a longer PFS (31 months vs. not reached), with no survival benefit due to the higher NRM rate (16% vs. 5%) [145]. A recent meta-analysis suggests lower rates of events in patients surviving at least 36 months post-allografting but until NRM rates are significantly decreased it will be difficult to justify upfront allograft in standard-risk patients (Figure 55.2) [146].

Alternative donor HCT

Ballen et al. reported on HCT outcomes for patients with MM undergoing unrelated donor HCT after high-dose conditioning. NRM was over 50% and PFS at 3 years was 15% [147]. Kröger et al. compared ATG with alemtuzumab in 73 patients with MM who underwent RIC with melphalan–fludarabine, followed by allogeneic HCT from HLA-matched or HLA-mismatched unrelated donors [148]. Alemtuzumab resulted in faster engraftment of leukocytes ($p = 0.03$) and platelets ($p = 0.02$), and in a lower incidence of acute graft-versus-host disease (GVHD) grade II–IV (24% vs. 47%, $p = 0.06$). More cytomegalovirus-seropositive patients in the alemtuzumab group experienced cytomegalovirus reactivation (100% vs. 47%, $p = 0.001$). The cumulative incidence of TRM at 2 years was 26% for ATG versus 28% for alemtuzumab ($p = 0.7$).

Figure 55.2 Meta-analysis of auto-RIC allogeneic versus tandem autologous trials. Source: Armeson et al. 2013 [146]. Reproduced with permission of Nature Publishing Group.

There was no significant difference in the estimated 2-year OS and PFS between ATG and alemtuzumab. Hence although feasible, alternative donor allografting should also be considered only in the context of a clinical trial primarily.

Future directions for allogeneic HCT in myeloma

Allogeneic SCT has been routinely associated with lower relapse rates than autografting [146]. Notwithstanding, relapse rates after allografting are still routinely 40% or more. Lenalidomide maintenance has also been used post-allogeneic transplant for myeloma. It theoretically appeared advantageous because of both its potential effects of enhancing the graft-versus-myeloma immune effect and also its direct anti-myeloma activity. The HOVON 76 phase II trial evaluated the safety and efficacy of lenalidomide 10mg daily following tandem autologous and non-myeloablative allogeneic SCT [149]. Thirty-five eligible patients were enrolled and 30 started on lenalidomide. However, after two cycles, 47% ($n = 14$) had to stop treatment, primarily due to flare of GVHD. Overall, 37% developed acute and 53% chronic GVHD. Despite the short duration and poor tolerability of therapy, 20% of patients upgraded response during lenalidomide therapy and an additional six patients improved their response after the lenalidomide was stopped, which made the total response rate 37%. The poor tolerability may be due in part to the timing of initiation of lenalidomide and also the dose. A US intergroup trial also used lenalidomide post-allogeneic transplant; results of this trial are awaited.

Conclusion

The treatment for myeloma continues to evolve. Thirty years ago, the standard treatment was melphalan and prednisone, with a response rate of only 40% and an average life expectancy of 3 years. During the last three decades, significant advances in therapy have been made. Today, transplantation-eligible patients receiving a standard induction therapy with thalidomide and dexamethasone followed by consolidation therapy with high-dose melphalan and one autologous HCT have more than an 80% chance of achieving a partial remission or better, and an average life expectancy of more than 5 years. Moreover, approximately one-third of patients treated will achieve CR, of whom 30% will remain without disease progression 10 years after HCT.

The advent of new agents such as bortezomib, carfilzomib, thalidomide, and lenalidomide, and the improved outcomes after induction therapy, should move the field to re-explore the role of high-dose melphalan as consolidation therapy for all patients with MM. Likewise, exploring strategies that could improve on the outcomes of high-dose melphalan are necessary. Post-transplantation therapy with consolidative chemotherapy and maintenance is also becoming an important adjuvant to improve outcomes. Although both allogeneic and autologous HCT can result in long-term disease control and potential cure, most patients still relapse. Therefore, caution needs to be exercised when recommending allogeneic HCT to patients with myeloma, since the risk–benefit ratio of this procedure still makes it difficult to recommend to all patients as upfront therapy. Likewise, recommending maintenance therapy to all patients regardless of their response to therapy or other risk factors will expose a substantial proportion of them to drug toxicities, who may have only a marginal benefit from this strategy. Hence further delineation of the prognostic value of gene expression profiling and other parameters will assist in developing true risk-tailored approaches for this disease, fulfilling the goal of delivering the longest life with the best quality and minimum burden of therapy for the greatest number patients with myeloma.

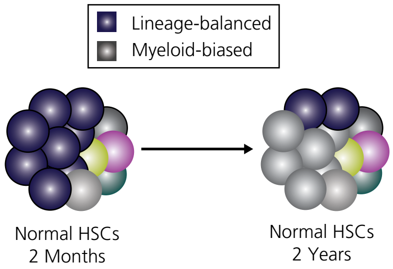
Figure 4.1 Hematopoietic lineage tree, showing cells at successive stages of differentiation with distinctive marker profiles (immunophenotypes) in mouse and human. The hematopoietic stem cell (HSC) has long-term reconstituting, self-renewing capacity; the multipotent progenitors have limited or no self-renewal leading to transient but multilineage reconstitution. CMP, common myeloid progenitor; CLP, common lymphoid progenitor; MEP, megakaryocyte/erythroid progenitor; GMP, granulocyte/macrophage progenitor; MkP, megakaryocyte progenitor; EP, erythroid progenitor; GP, granulocyte progenitor; MacP, macrophage progenitor; Pro-DC, dendritic cell progenitor; Pro-B, B lymphocyte progenitor; Pro-T, T lymphocyte progenitor; Pro-NK, natural killer cell progenitor.



Lineage-balanced
Myeloid-biased
Normal HSCs
2 Months
Normal HSCs
2 Years

Figure 4.5 At birth, most of the hematopoietic stem cell (HSC) clones in mice are lineage-balanced, that is, equally capable of generating various lineages. However, with age, clones biased towards generating myeloid lineages (myeloid-biased) predominate, due to either clonal selection or epigenetic changes in the originally lineage-balanced clones.

Figure 4.6 Images from Gene Expression Commons (https://gexc.stanford.edu/) showing absolute comparison of the array data for particular genes (*EpoR, c-Mpl, IL-7Rα*, and *c-Ebpα*). Raw microarray data are individually normalized against a large-scale common reference, then mapped onto each probe-set metaprofile. This strategy enables profiling of absolute expression levels of all genes on the microarray.

Leukemic stem cell

Figure 4.11 Comparison of stem cell self-renewal during normal hematopoiesis and leukemic transformation. During normal hematopoiesis, the signaling pathways that regulate self-renewal are tightly controlled, allowing proper differentiation to each of the mature blood cell lineages (top). Accumulation of mutations in the self-renewing hematopoietic stem cells (HSCs) over time until dysregulated self-renewal ability is attained and leukemia propagation is initiated. Dysregulation of self-renewal mechanisms in transformed cancer stem cells leads to uncontrolled self-renewal and the production of leukemic blast cells. The leukemic population capable of sustaining disease is often distinct from the blast population, and may reside in the stem cell or progenitor cell compartment. Importantly, if the transformation event occurs in a progenitor cell, it must endow the progenitor cell with the self-renewal, because the progenitors would otherwise differentiate.

Figure 4.12 Clonal progression of preleukemic mutations in hematopoietic stem cell (HSC) clones, followed by emergence of the leukemia stem cell (LSC) in the multipotent progenitor (MPP) stage in three cases of FLT3td acute myeloid leukemia (AML) [84]. Exomic sequencing of the AML cells and T cells from the same patients allow listing of the mutations specific to the AML. Individual HSCs were isolated from the 3 patients and grown to colonies with hematopoietic growth factors, and the colonies analyzed with DNA primers specific for each of the mutations in the LSCs. Shown are the normal HSC clones (grey) and mutant HSC clones (with each successive color – blue, green, yellow – indicating the addition of a new mutation). Leukemic HSC clones (red) finally have all mutations. A TET2 loss of function mutation via a stop codon was the earliest preleukemic HSC event in 2 of the 3 patients (b) and (c). In the same individuals, the next event is the loss of TET2 by another stop codon in the other TET2 allele. Following that are clones with 3, or 4 or n mutations in the 3 patients. In all 3 the FLT3 internal tandem repeat occurred as the final mutation before the LSCs emerge. It is interesting that in 2 patients the loss of all TET2 function, which regulates CMEpG to hydroxymethyl cytosine, an epigenetic modifier of the CpG methylome, occurs before any of the other mutations. Med.* 2003; **44**: 437–445. Reproduced with permission of the Society of Nuclear Medicine.

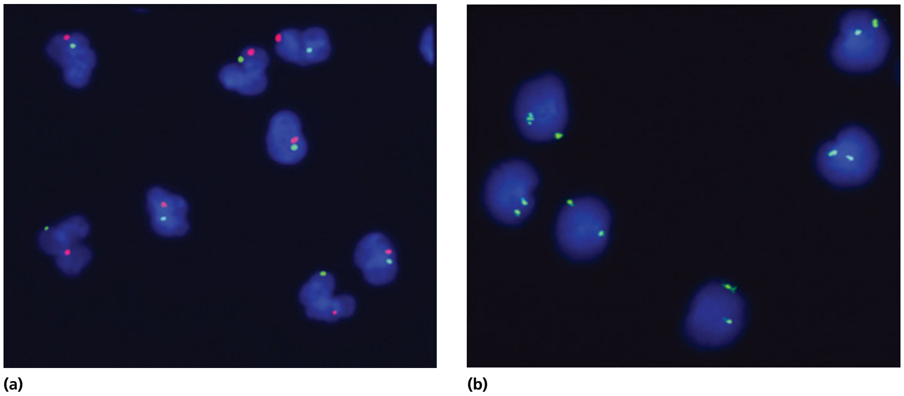

Figure 24.1 Assessment of chimerism in sorted granulocytes (a) and leukemic blasts (b) by dual-color fluorescence in situ hybridization (FISH). Hybridization was carried out with a biotin-labeled Y chromosome-specific DNA probe and a digoxigenin-labeled X chromosome-specific DNA probe. Hybridization was detected with Texas Red-conjugated avidin and fluorescein-conjugated antibody against digoxigenin. Cells were counterstained with 4′,6-diamidino-2-phenylindole (API). Male cells contain a single red fluorescent spot and a single green fluorescent spot, whereas female cells contain two green fluorescent spots and no red fluorescent spots. In this case, granulocytes were derived from a male donor and leukemic blasts were derived from the female recipient.

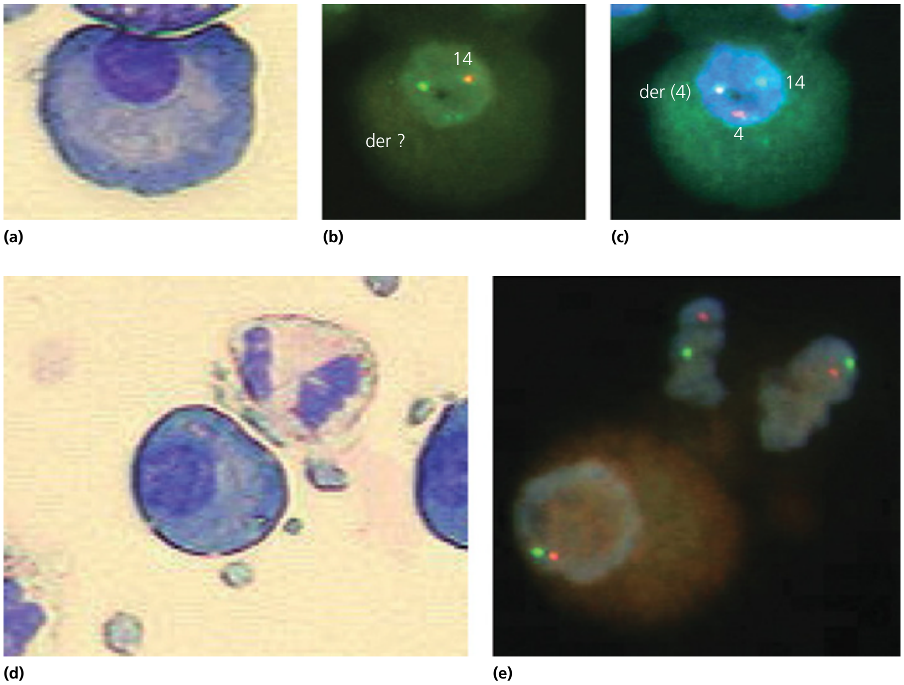

Targeted scanning with CD19 monoclonal antibody

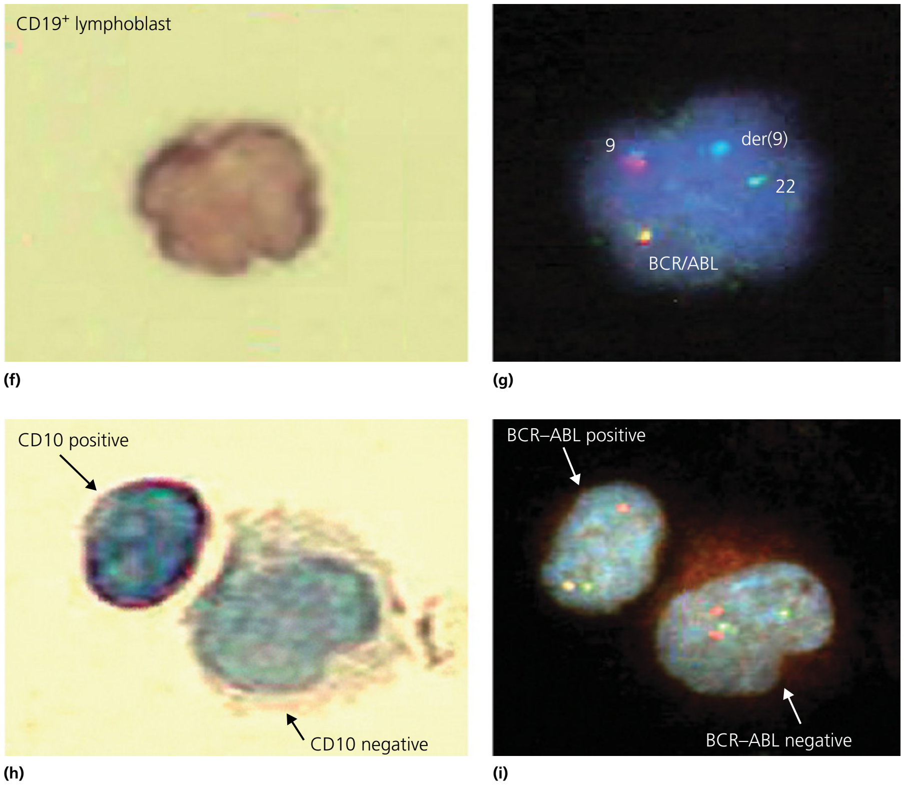

Figure 25.2 Plasma cell-specific fluorescence in situ hybridization (FISH) analysis. (a–e) Cytospin slides are made from the bone marrow aliquot and stained with May–Grünwald stain. After the cells have been mapped to the slide, the slide is destained and hybridized with the selected DNA probe. For details, see [5]. (a) A plasma cell that has been mapped. This same cell is seen in (b), showing a variant immunoglobulin H (*IGH*) pattern using a dual-color *5′IGH/3′IGH* break-apart probe. Once an *IGH* gene rearrangement is found in a patient with multiple myeloma, the same slide is rehybridized to determine its partner chromosome in the IGH translocation. (c) A fusion signal is detected with the *FGFR3* (fibroblast growth factor receptor-3)/*IGH* probe indicating the derivative chromosome 4 of the t(4;14) or der(4)t(4;14). The second fusion that would have indicated the der(14)t(4;14) is not present in this patient, the result of loss of the derivative 14 chromosome. In another slide from this patient [(d) and (e)], monosomy 13 is shown in the neoplastic plasma cells, but the segmented neutrophil adjacent to the plasma cells shows both chromosome 13 signals (one each in each of the segments of the nucleus). The chromosome 13 probe set used was composed of D13S319 probe (red), which maps to 13q14.3, and the *LAMP1* (lysosomal-associated membrane protein-1)/13q34 reference probe labeled in green. Sequential immunohistochemistry (IHC)/FISH is shown in (f)–(i). (f) A CD19$^+$ lymphoblast that is *BCR/ABL1* fusion gene positive (g), indicating residual disease and not a hematogone. Similarly, (h) and (i) show the cell that is CD10$^+$ is positive for the *BCR/ABL1* fusion gene, and the CD$^-$ cell is negative for the *BCR/ABL1* fusion gene. The *BCR/ABL1* probe used for the sequential IHC/FISH studies was the single fusion probe spiked with 9q34/argininosuccinate synthetase gene probe labeled in Spectrum aqua. All probes were obtained and reproduced with permission from Abbott Molecular Inc. (Des Plaines, IL, USA).

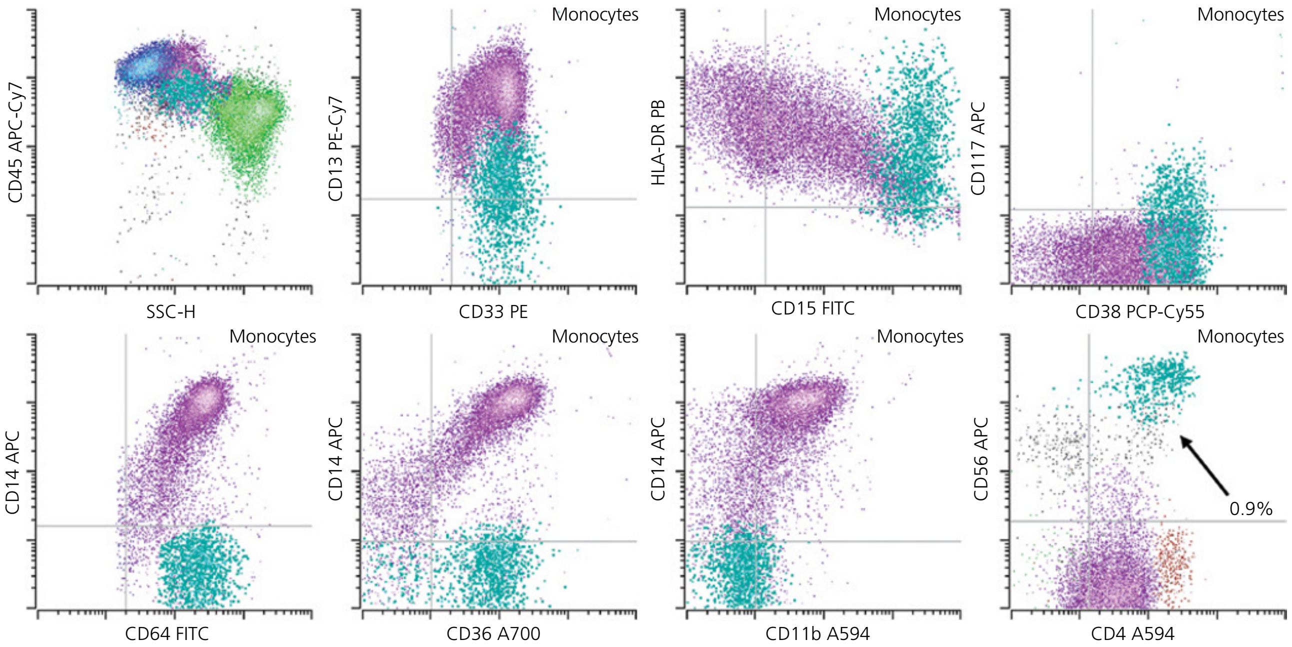

Figure 25.3 Flow cytometry assays for detection of minimal residual disease. Leukemia samples can be labeled with multiple fluorescent antibodies, and cells can be distinguished by the size of the cell and the types of antibody that bind the cell surface. Normal hematopoiesis has very stereotypical cell antigen expression linked to differentiation; leukemia cells are distinguished by inappropriate expression patterns of these antibodies. In the example, a residual acute monocytic leukemia is analyzed with multiple antigens. In the bottom left panel, the sample shows an inappropriate expression of CD56 and CD4 consistent with residual disease. In this example, these cells made up 0.9% of the total nucleated cells. Figure 25.4 Quantitative polymerase chain reaction (PCR). The cartoon shows the principle behind the two most popular quantitative approaches: the Taqman (ABI) and the LightCycler (Roche). In the Taqman reaction (I), the probe is a 5′ reporter dye and a 3′ quencher molecule. When the probe is intact, the quencher blocks laser excitation of the reporter. During PCR, the 5′ exonuclease activity of Taq polymerase releases the reporter, which, free from the quencher, is excited by the laser detection system. In the LightCycler system (II), annealing of juxtaposition probes during PCR synthesis allows for the transfer of resonance energy that can be stimulated by the laser and detected. In both systems, a standard curve is generated that plots dilutions of the standards versus the PCR cycle number at which a threshold signal is obtained (middle panel). The starting amount of target in unknown samples is thus detected by a back-calculation of cycle threshold in the unknown (Ct) against the standard curve. Source: Reproduced with permission of Dr. John Goldman.

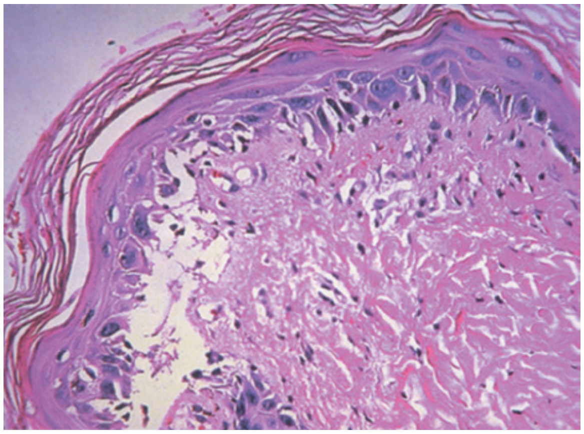

Figure 26.1 Skin biopsy from a recipient of identical twin marrow who had received a single 15 mg/kg dose of dimethylbusulfan 15 days previously. The epidermal separation, keratinocyte atypia, and scanty lymphoid dermal infiltrate can also be seen in GVHD.

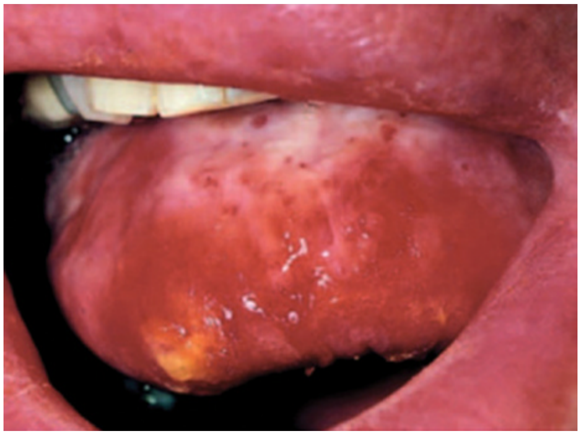

Figure 26.2 Acute glossitis 1 day post-HCT after a conditioning regime of 60 mg/kg of cyclophosphamide (CY) followed by 12 Gy of fractionated total body irradiation (TBI). There is early mucosal damage with severe erythema and focal atrophy.

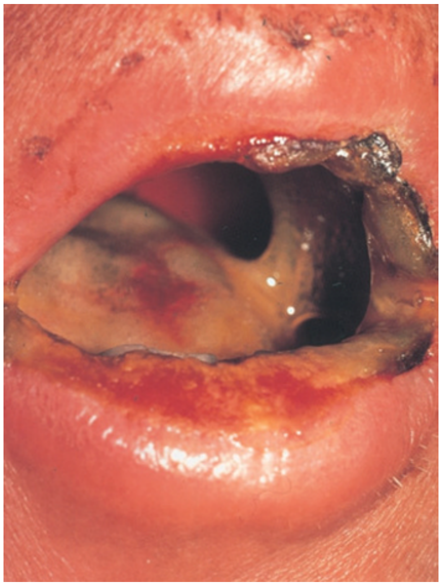

Figure 26.3 Severe mucositis of lips and tongue with pseudomembranous exudate 20 days after HCT following conditioning with TBI and chemotherapy. Similar changes may be present with severe acute GVHD or herpetic infection.

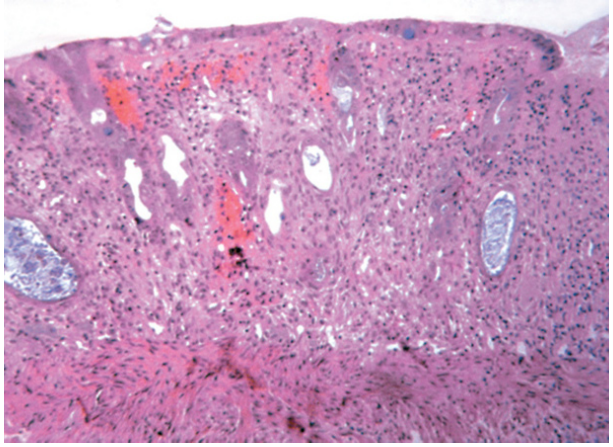

Figure 26.4 Effect of cytoreductive therapy on colonic mucosa, day 7. This biopsy specimen was taken following therapy with busulfan (BU), CY, and TBI (12 Gy). There has been obliteration of almost all epithelial cells, leaving cystic crypt remnants. (H&E with Alcian Blue counterstain.)

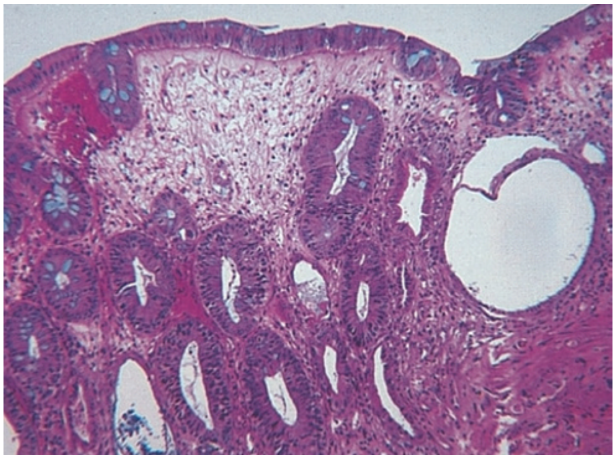

Figure 26.5 Recovery from the effects of cytoreduction therapy on colonic mucose, day 16. This repeat biopsy from the same patient as in Figure 26.4 indicates that regeneration is occurring, although some cystic crypts remain. (H&E with Alcian Blue counterstain.)

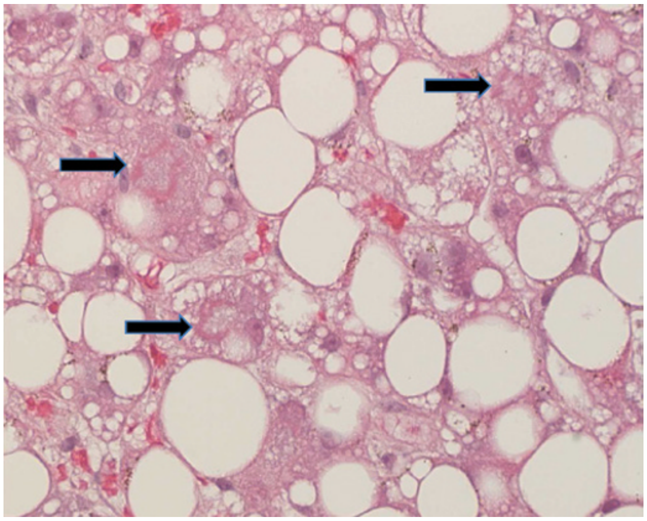

Figure 26.6 H&E-stained liver biopsy demonstrating changes of non-alcoholic steatohepatitis (NASH) with extensive macro- and lesser amounts of microsteatosis, hepatocyte ballooning, and focal Mallory body formation (arrow).

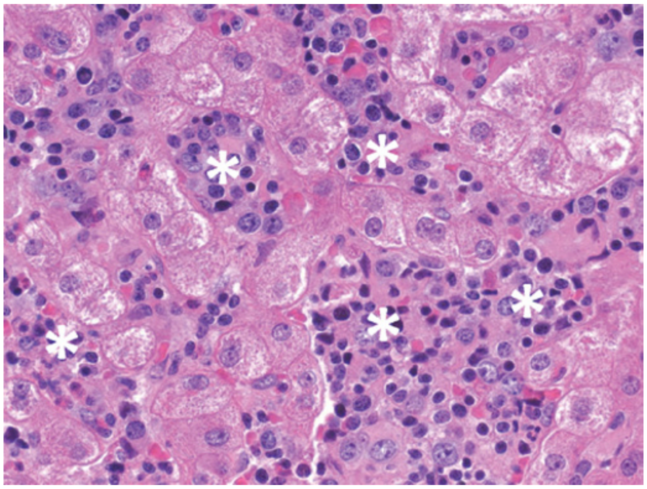

Figure 26.7 H&E-stained section of a pre-transplant liver biopsy from a patient with myelofibrosis. The hepatic sinusoids (white asterisk) are expanded by a mixed cellular infiltrate of hematopoietic precursors.

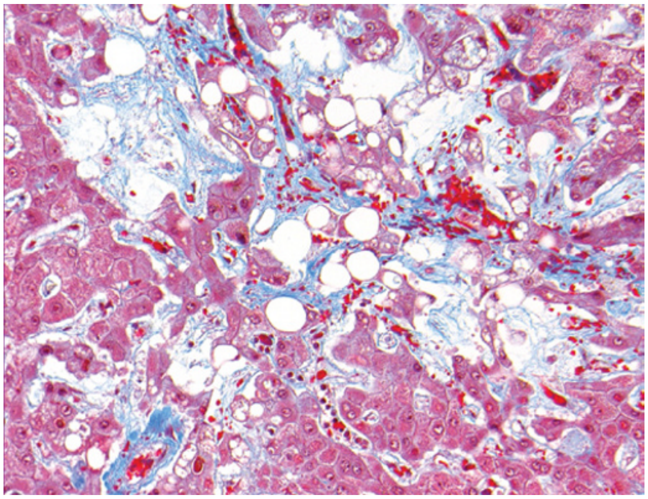

Figure 26.8 Fatal gemtuzamab ozogamicin (Mylotarg™)-associated sinusoidal obstruction syndrome. The obliterated central venule is surrounded by focal sinusoidal fibrosis. (Trichrome stain.)

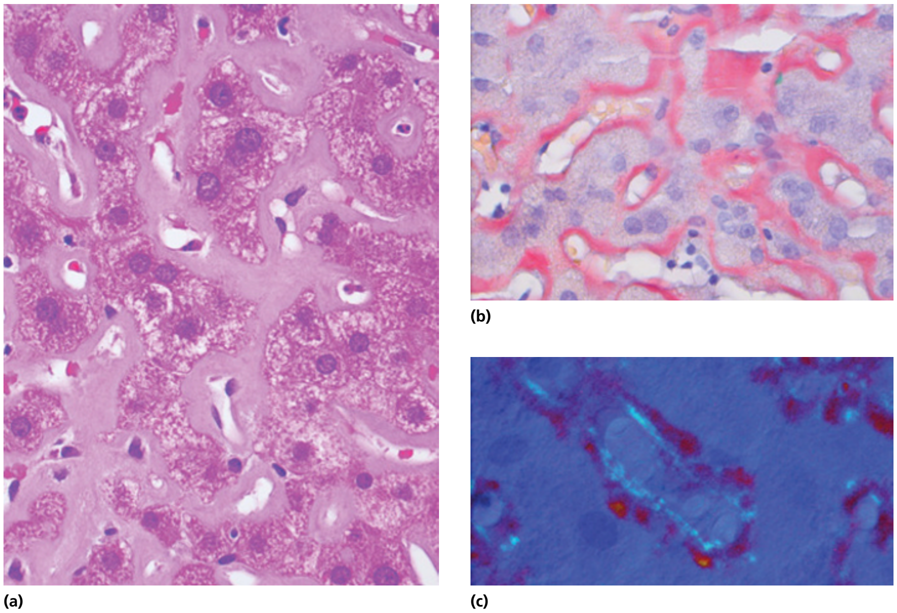

Figure 26.9 (a) H&E-stained section of a pre-transplant liver biopsy demonstrating extensive amyloid deposition in the liver sinusoids. (b) Congo Red stain of the same liver biopsy, with the sinusoidal amyloid deposit highlighted by salmon-pink staining. (c) Congo Red stain under polarized light: the sinusoidal amyloid deposit shows apple-green birefringence.

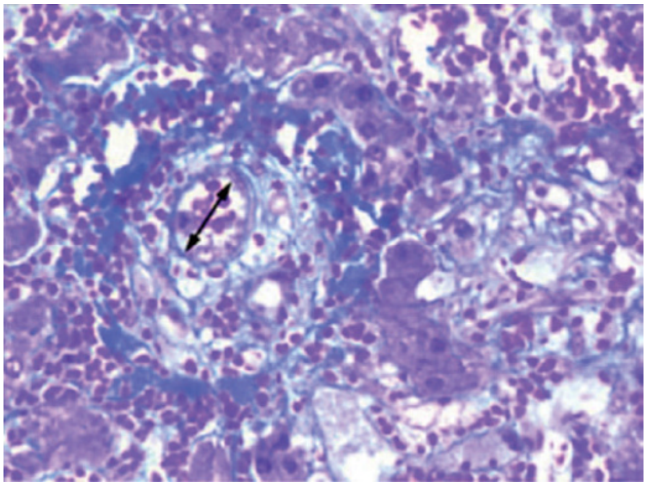

Figure 26.10 Hepatic sinusoidal obstructive syndrome (SOS) 95 days post-HCT for malignancy. The trichrome stain shows the blue outline of a hepatic venule with marked luminal narrowing (arrow shows lumen diameter) caused by subendothelial trapping of red cells. The hepatocytes of acinar zone 3 are severely disrupted. When the clinical diagnosis of hepatic SOS is uncertain, it may be confirmed by a transvenous liver biopsy with measurement of an elevated gradient between wedged and free hepatic venous pressures.

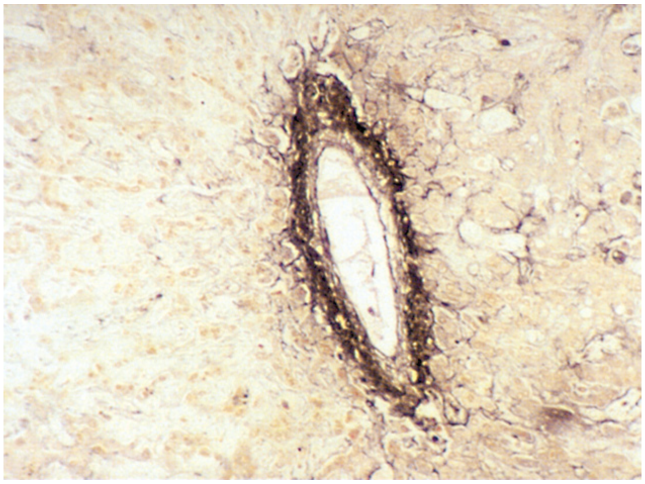

Figure 26.11 Early hepatic SOS showing perivenular staining for procoagulants. Immunohistochemical staining for factor VIII (von Willebrand) demonstrates post-sinusoidal obstruction corresponding to the endothelium-lined pores through which the sinusoids drain into the venules. Immunostaining for fibrin localizes in the same regions. These observations provide some of the rationale for using anticoagulation and anti-thrombotic therapy for hepatic SOS.

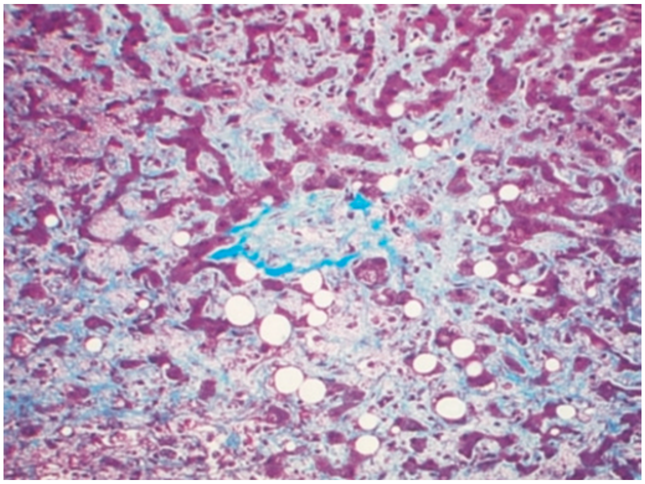

Figure 26.12 Late hepatic SOS, day 63. The trichrome stain demonstrates fibrotic obliteration of the venous lumen with extensive fibrosis in surrounding sinusoids. The resulting vascular obstruction produced intractable ascites. Immunohistochemical stains at this stage reveal extensive deposition of collagen, while fibrin and other blood procoagulants are no longer identifiable.

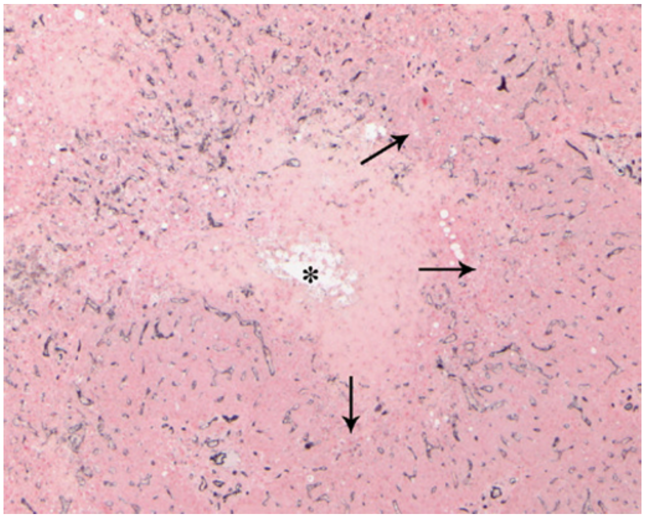

Figure 26.14 CD 31 immunostain of liver with fatal SOS. There has been partial to complete loss of sinusoidal endothelial staining of the hepatic cords in zone 3 (arrows) which surround the subtotally occluded venule lacking an endothelium (asterisk).

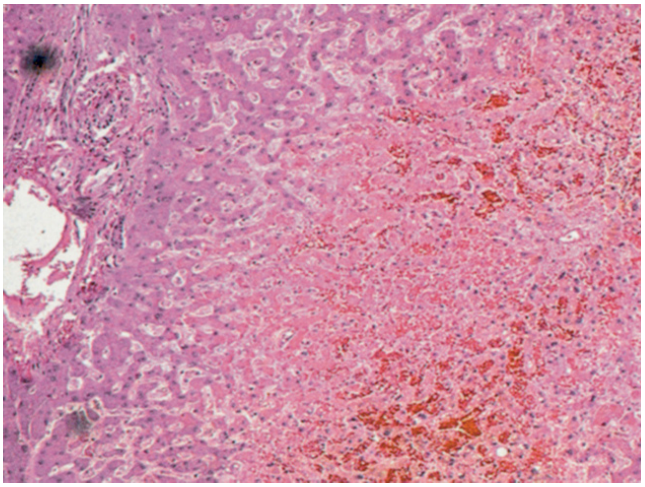

Figure 26.13 Fatal hepatic SOS at autopsy 12 days post BMT for leukemia. At this low magnification, the H&E-stained section demonstrates striking congestion, hemorrhage, and hepatocyte disruption in zone 3 (centrilobular) of the liver acinus toward the right. The portal space and surrounding acinar zone 1 on the left are well preserved. These early severe hepatic SOS lesions at times can be identified with the H&E stain after tissue fixation with B5 or methyl Carnoy's fixative. However, stains for connective tissue are more effective.

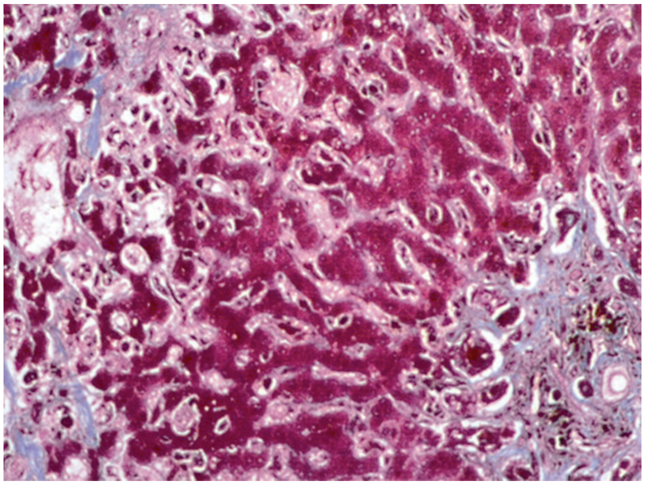

Figure 26.15 Hepatic SOS and coexisting GVHD, day 26. On this trichrome stain, the two most common liver problems after HCT can be differentiated by the zone of the liver acinus that they affect. The expanded portal space in the lower right demonstrates changes from GVHD, including fibrosis, proliferation of atypical cholangioles along the limiting plate, and destruction of small interlobular bile ducts. The SOS lesion along the left margin shows striking collections of embolized hepatocytes beneath the endothelial basement membrane.

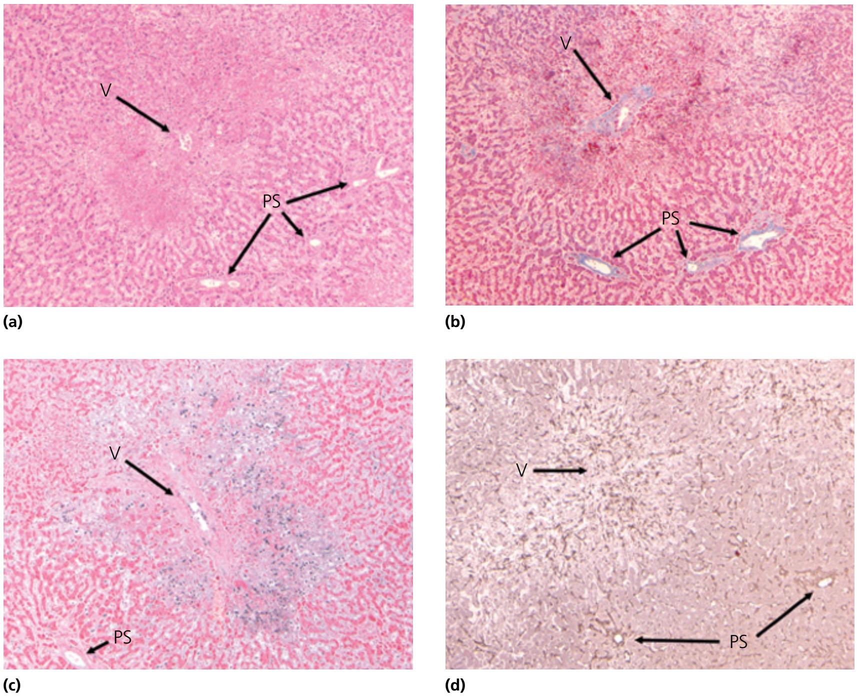

Figure 26.16 Fatal SOS. (a) H&E stain demonstrates a large perivenular zone of hemorrhagic necrosis with destruction of hepatocyte cords surrounding the damaged venule (V); the areas around the portal spaces (PS) are spared. (b) Trichrome stain demonstrates the subtotal occlusion of the venular lumen by collagen and extracellular matrix. (c) Immunostain Mac 387 for macrophage/monocytes demonstrates a zone of cells at the interface of the viable and necrotic hepatocytes. (d) Smooth muscle actin immunostain demonstrates marked expansion of hepatic stellate cell processes within the damaged sinusoids surrounding the venule.

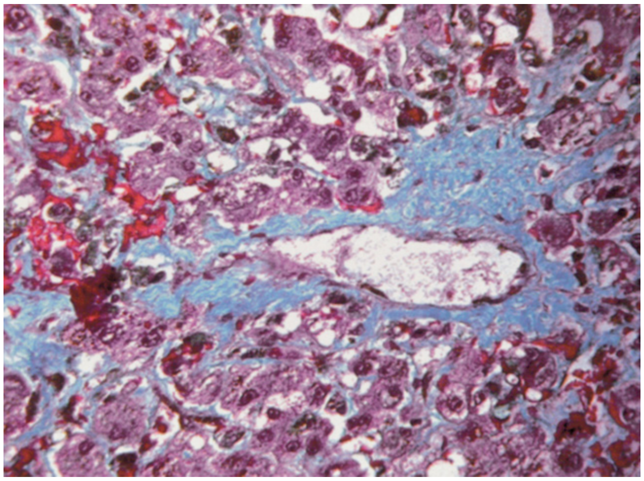

Figure 26.17 Hepatic phlebosclerosis, day 96. Eccentric thickening of the venular wall without striking luminal narrowing was associated with an early liver toxicity syndrome. The patient had received a 5-day infusion of high-dose cytosine arabinoside (Ara-C) followed by CY and TBI. Liver function abnormalities developed prior to the infusion of marrow. Changes of phlebosclerosis were widespread, but there were no identifiable hepatic SOS lesions at autopsy. (Trichrome stain.)

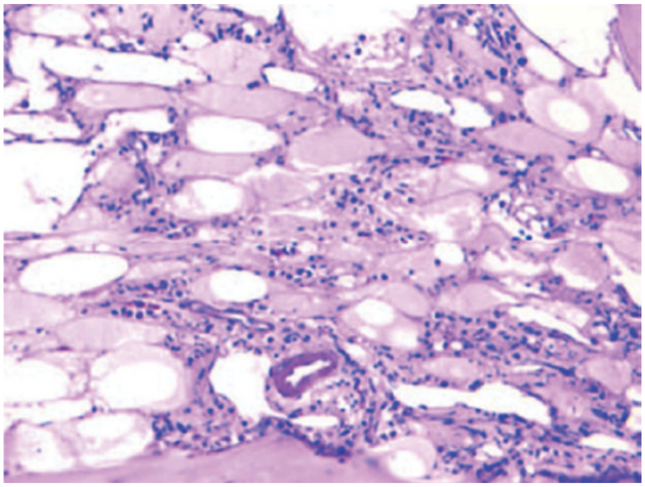

Figure 26.18 Markedly hypocellular marrow without evidence of engraftment, day 7. The interstitial fluid accumulation, fat necrosis, and iron deposition are consistent with chemoirradiation damage.

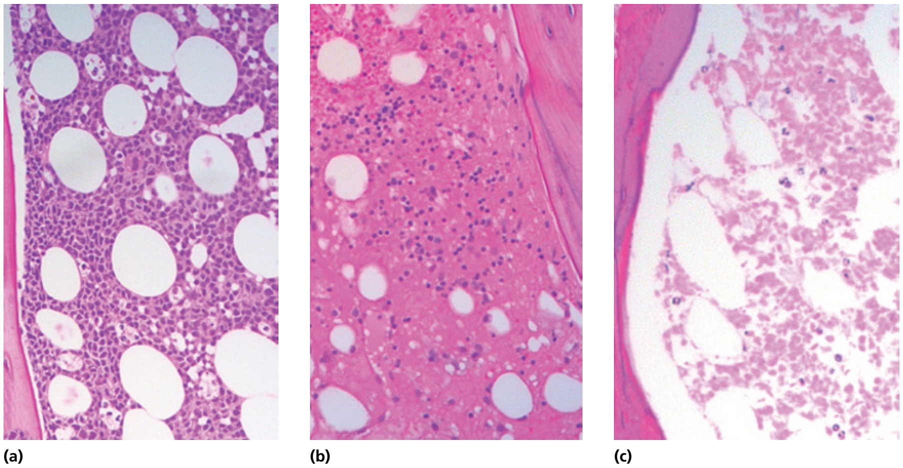

Figure 26.19 Same patient as in Figure 26.18 with acute myeloid leukemia: (a) diagnostic marrow with 96% blasts; (b) day 7 marrow after chemoreduction showing serous atrophy; (c) day 21 marrow with persistent pancytopenia showing extensive necrosis with only scattered neutrophils.

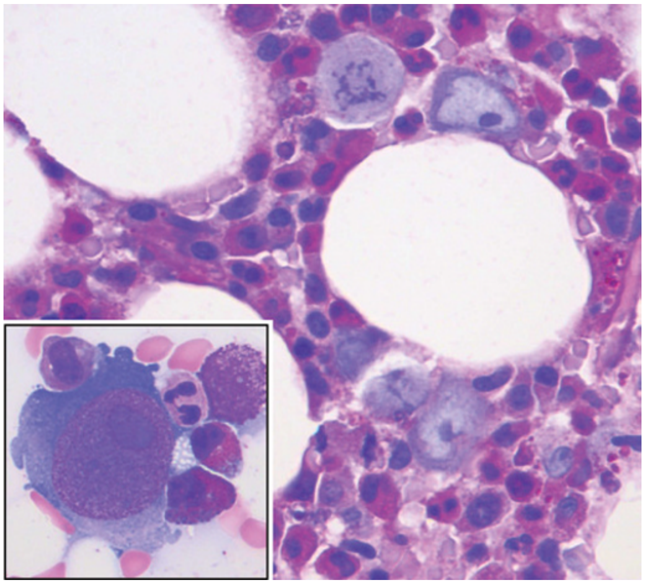

Figure 26.20 Pre-transplant marrow biopsy stained with periodic acid–Schiff (PAS) stain from a patient with diffuse large B-cell lymphoma with persistent anemia and quantitative Parvovirus virus PCR result of 13 billion. The PAS-stained marrow shows abnormally enlarged PAS negative proerythroblasts with prominent nucleoli and a marked erythroid hypoplasia. The inset at bottom left shows a Wright-stained aspirate smear with a markedly enlarged proerythroblasts with a prominent nucleoli.

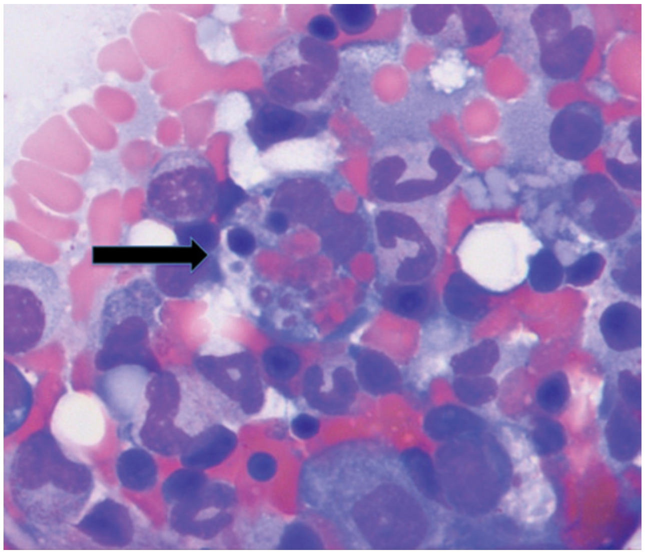

Figure 26.21 A Wright–Giemsa-stained marrow aspirate smear from a patient with large cell transformation of mycosis fungoides day 174 post-HCT with hemophagocytosis. A hematophagocytic macrophage with engulfed red blood cells and erythroid precursors in varying stages of degeneration is indicated by the back arrow.

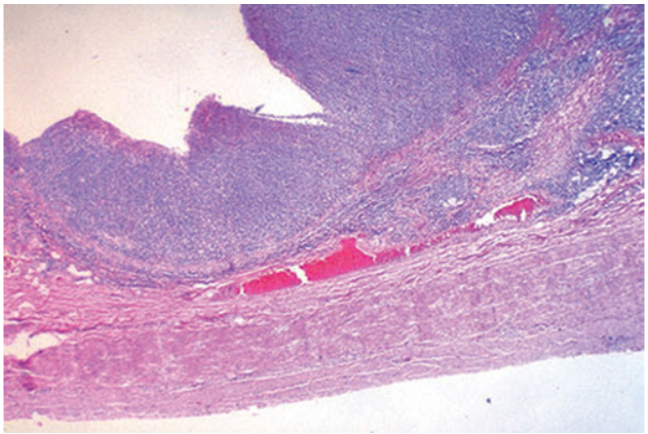

Figure 26.22 EBV-associated lymphoma infiltrating the intestinal mucosa in a boy treated for GVHD with cyclosporine and a monoclonal antibody to T-lymphocytes. Although the GVHD improved, large bizarre cells with atypical nuclei characteristic of a high-grade lymphoma rapidly formed tumor nodules in liver, spleen, lymph nodes, and mesentery.

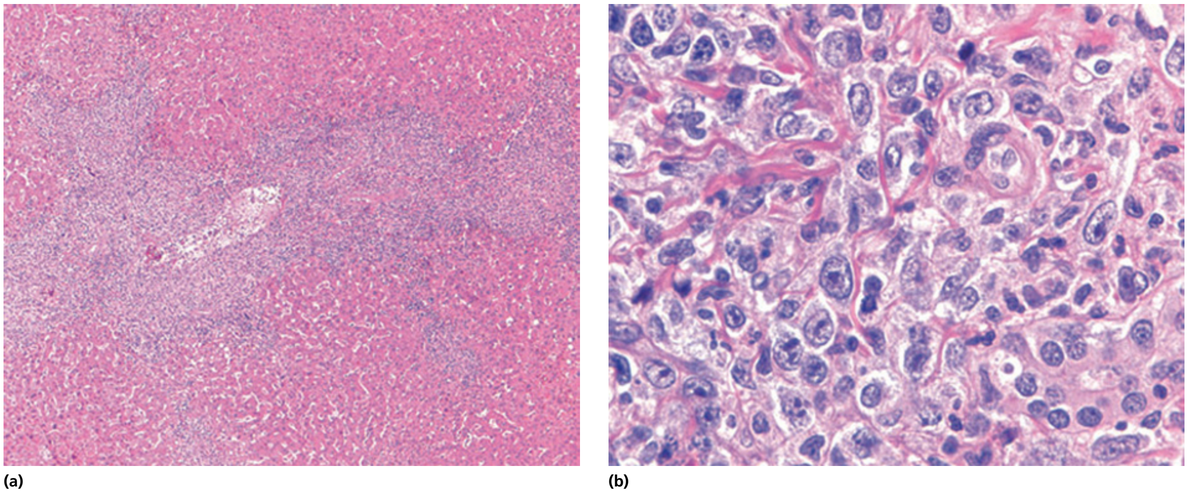

Figure 26.23 (a) Post-transplant EBV lymphoma. Following treatment for liver GVHD, the liver function abnormalities recurred. At low power, the portal space contains a prominent infiltrate that extends outwards into the periportal zone. (b) In the same case, higher magnification shows the large atypical immunoblastic cells that were positive for CD20 and EBER staining.

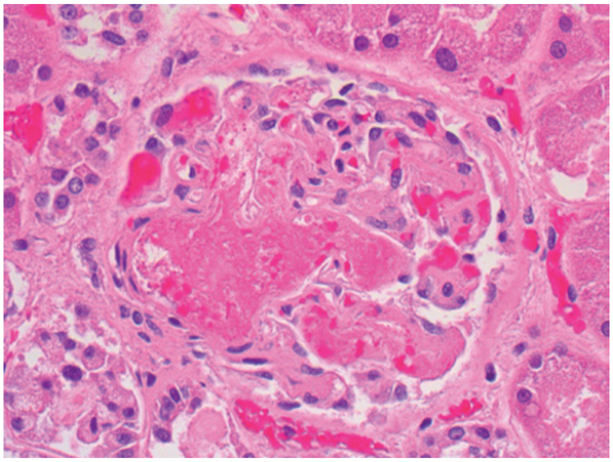

Figure 26.24 Kidney specimen stained with H&E showing transplant-associated microangiopathic/hemolytic (TAM) syndrome in a patient with AML progressed from MDS after HCT and died on day 21. There is thrombi formation in the capillary loops of the glomerulus, and characteristically showing involvement of the afferent vessel.

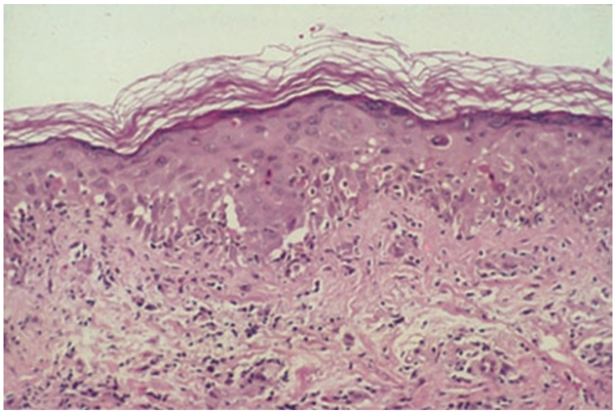

Figure 26.25 Acute skin GVHD, day 28 after mismatched allogeneic HCT. The epidermis demonstrates a prominent lichenoid reaction involving the tip of the rete ridge in the center of the specimen, a location of epithelial stem cells within the epidermis.

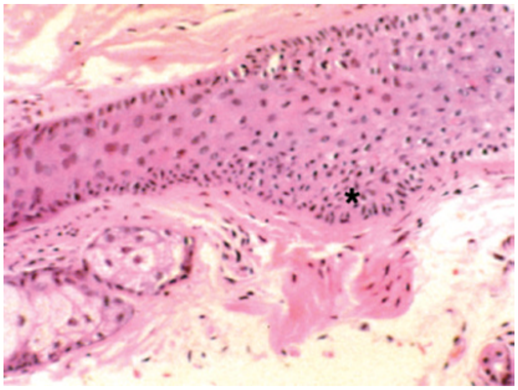

Figure 26.26 Early skin GVHD involving the parafollicular bulge region of the pilar unit. Note the small numbers of mononuclear inflammatory cells which infiltrate the parafollicular bulge area (*) near the arrector pilorum muscle in association with apoptotic bodies.

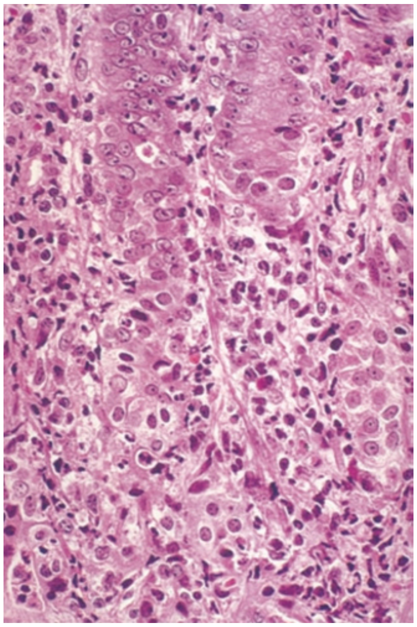

Figure 26.27 Gastric biopsy with GVHD, day 35. Several studies have shown that of all upper endoscopic biopsy sites, the stomach most frequently shows histologic changes of GVHD. In the area shown here, large numbers of lymphocytes infiltrate the lamina propria and the basilar portions of the gastric crypts. There is apoptosis of crypt epithelial cells and frank early crypt destruction. Inflammation and apoptosis of this intensity are not required for the diagnosis of gastric GVHD. More subtle yet still diagnostic alterations are illustrated in Figures 26.50 and 26.51.

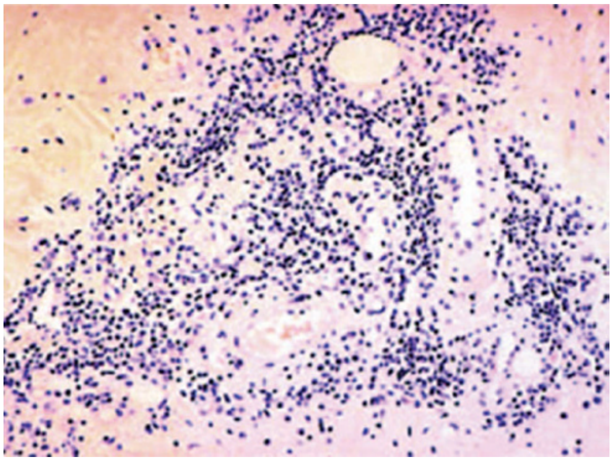

Figure 26.28 Atrophy and fibrosis of thymus associated with chronic GVHD in a 13-year-old, day 350. The patient had not received immunosuppressive drugs, so the destruction was presumably the result of chronic GVHD activity.

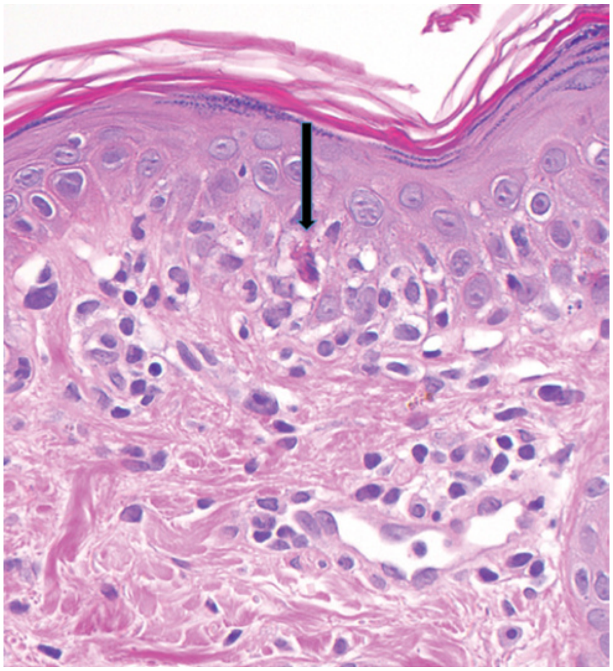

Figure 26.30 H&E stain of a skin biopsy from a, HCT patient day 25 with GVHD. There is mild spongiosis, basal vacuolization, lymphocytic inflammatory cells, and a few scattered apoptotic cells (arrow).

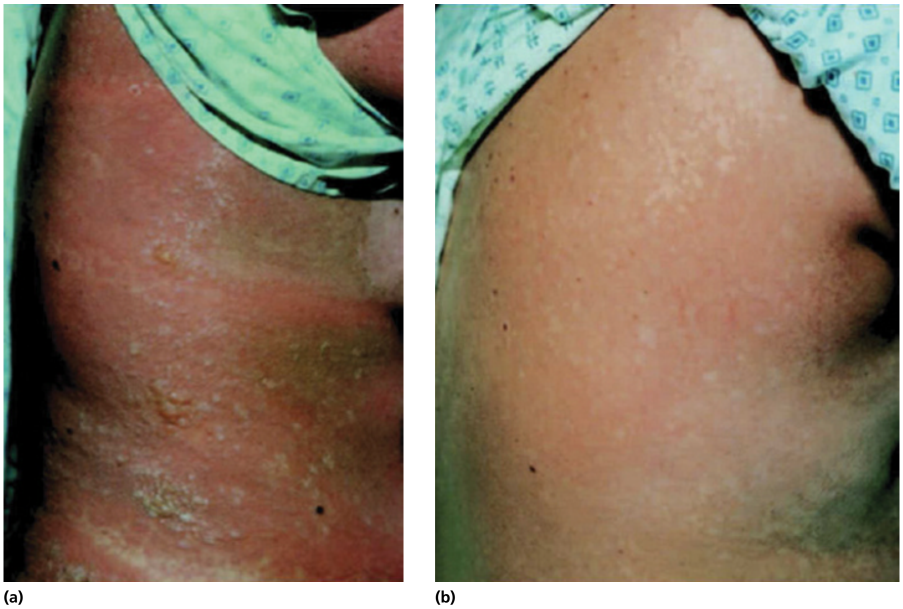

Figure 26.32 Before and after therapy photographs of the right lateral torso from the two different time points in an HCT patient: (a) erythema and desquamation before treatment for acute GVHD, day 27; (b) virtually normal skin with focal depigmentation after treatment for acute GVHD, day 74.

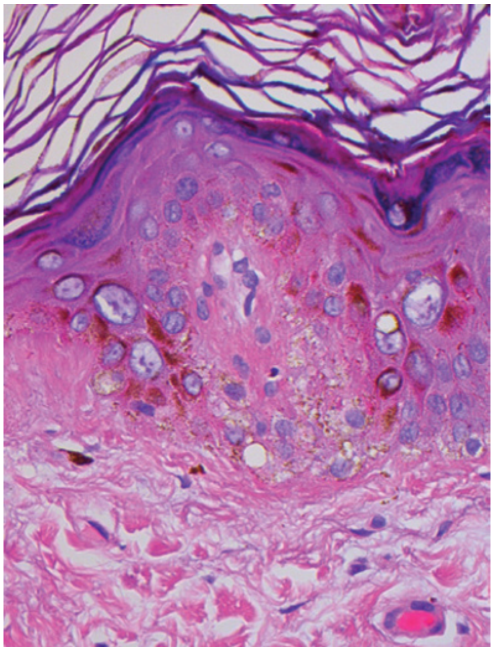

Figure 26.33 Severe keratinocyte dysplasia in a patient with myelodysplastic syndrome who is day 76 after myeloablative HCT with busulfan-based chemoreduction therapy.

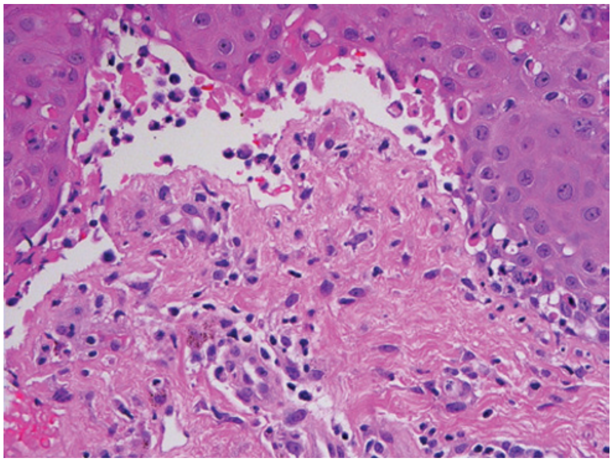

Figure 26.34 Skin biopsy from a patient who is day 36 after HCT with an erythematous non-pruritic rash involving 40% of the total body surface including the upper trunk, arms, head, and a few spots on the legs. This biopsy shows confluent basal cell necrosis with separation at the dermal epidermal junction, a histologic pattern more consistent with Stevens–Johnson type of drug eruption.

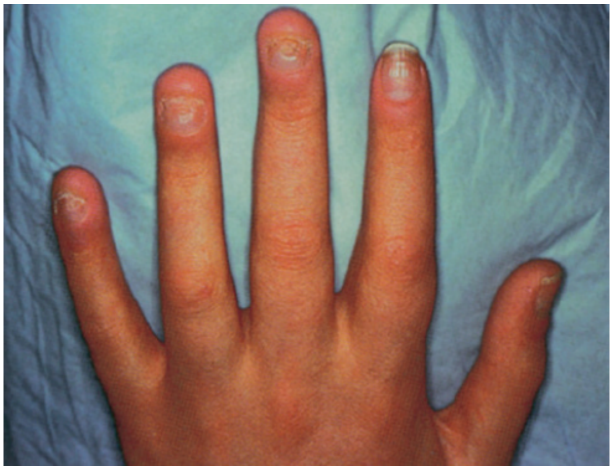

Figure 26.35 Periungual erythema and onychodystrophy 100 days after allogeneic BMT in a patient with ocular sicca and oral lesions of chronic GVHD.

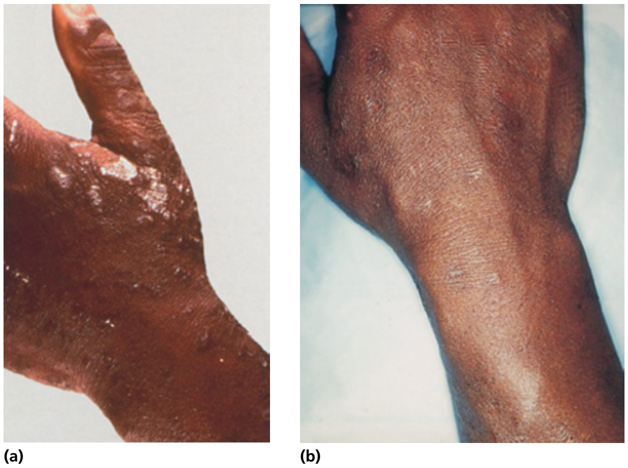

(a)

(b)

Figure 26.36 Photographs from a 24-year-old African American male who received an human leukocyte antigen (HLA)-identical HCT: (a) hand with lichen planus-like chronic GVHD day 220 post-HCT; (b) forearm after treatment, day 770 post-HCT.

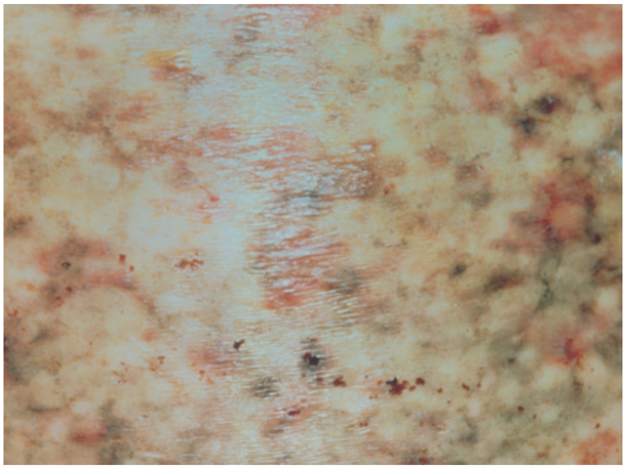

Figure 26.37 Poikiloderma in late chronic GVHD in a 2-year-old girl, day 450. Thinning of the epidermis and dermis is present along with telangiectasia and reticulated pigmentation.

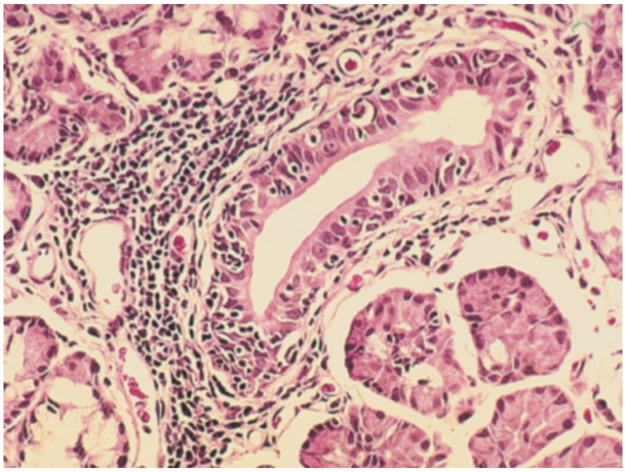

Figure 26.40 Oral labial biopsy with early chronic GVHD, day 92. The minor salivary gland exhibits a periductal mononuclear inflammatory infiltrate involving the duct epithelium, in which there is focal epithelial apoptosis. There is inflammation of adjacent acini. This process leads to fibrosis with acinar atrophy in lobules drained by the affected ducts. The squamous surface epithelium (not present here) showed grade II lesions similar to those previously illustrated in skin (see Figure 26.25). The lip biopsy is valuable in the diagnosis and staging of chronic GVHD because it frequently mirrors destructive inflammatory changes in lacrimal, tracheal, and esophageal glands as well as bile ducts.

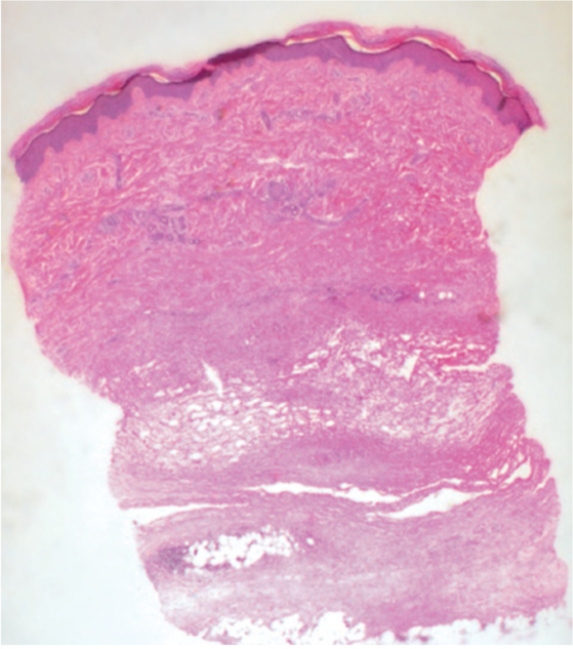

Figure 26.41 Late chronic GVHD of skin, day 959. As this patient's GVHD progressed, the epidermis became atrophic, with straightening of the dermal–epidermal junction. All dermal appendages were destroyed. The reticular dermal collagen became increasingly sclerotic. A panniculitis seen at the base of the specimen resulted in fibrosis of the subcutaneous fat and large vessels. This histologic picture corresponds to the dense hidebound and sclerodermatous changes of late chronic GVHD.

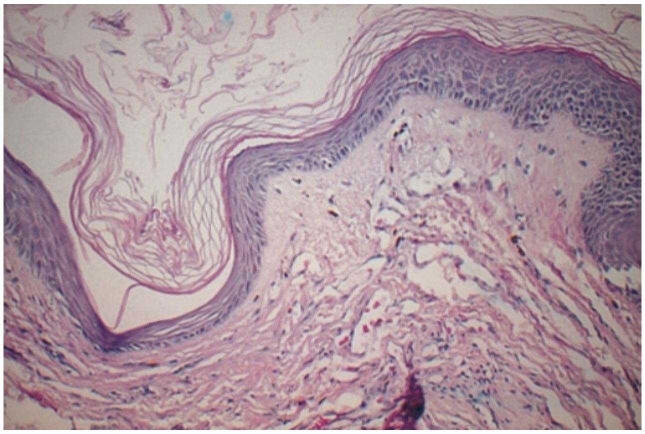

Figure 26.43 Poikiloderma, day 719. The patient was treated vigorously for extensive chronic GVHD with corticosteroids plus several other immunosuppressive agents. Although he had extensive dyspigmentation, telangiectasia, and atrophy of the skin, there were no contractures or scleroderma. Histologically, the epidermis is atrophic, with loss of rete ridges. The fibrotic papillary dermis contains many telangiectatic vessels, and there is intracellular melanin pigment. The deep dermal sweat glands remain despite earlier inflammatory involvement, and the reticular dermal collagen is normal.

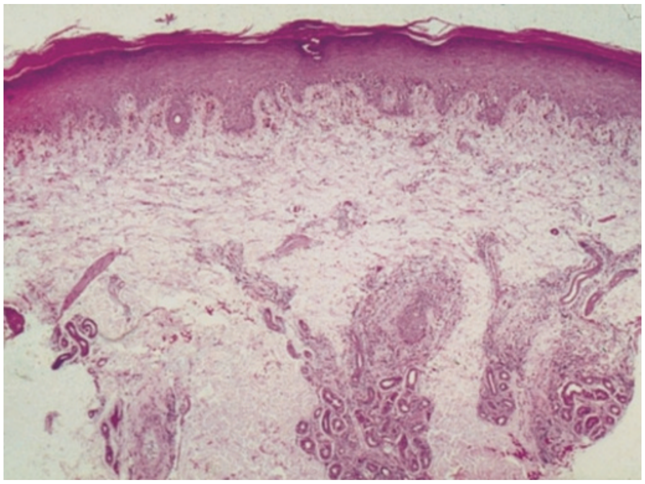

Figure 26.44 Lichenoid early chronic GVHD of skin, day 233. Biopsy of a papulosquamous lesion from the posterior neck demonstrates the characteristic features of the lichen planus-like type of chronic cutaneous GVHD. The thickened epidermis displays hyper- and parakeratosis, hypergranulosis, and acanthosis. The extensive destruction along the dermal–epidermal junction results in sawtooth-like changes of the rete ridges, mimicking lichen planus. The papillary dermis has considerable perivascular inflammation. The lichenoid reaction also involves the hair follicles and eccrine glands seen deep in the reticular dermis. At this stage, treatment can prevent progression to fibrosis (see Figure 26.41).

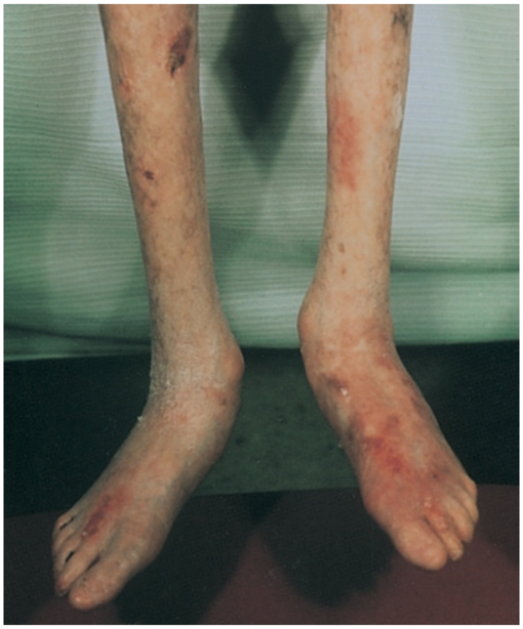

Figure 26.45 Generalized scleroderma with atrophy, sclerodactyly, and joint contracture, day 540 after HLA-identical BMT.

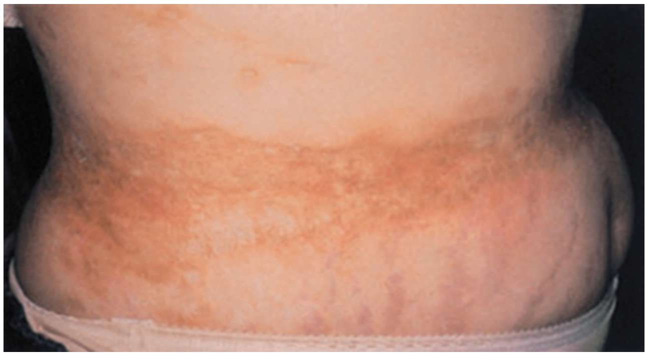

Figure 26.46 Localized late phase of chronic GVHD resembling morphea with atrophic plaque formation, induration, and peripheral hyperpigmentation, day 684.

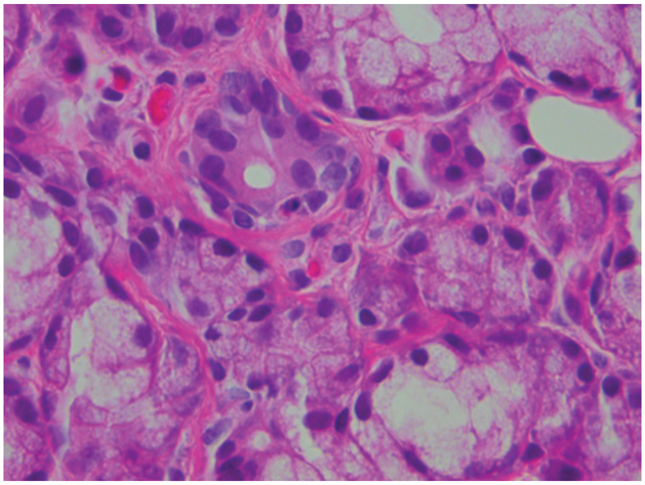

Figure 26.48 GVHD in a salivary gland biopsy from a patient with aplastic anemia day 81 after HCT on with apoptotic cells in the intercalated ducts and architectural distortion with nuclei disarray.

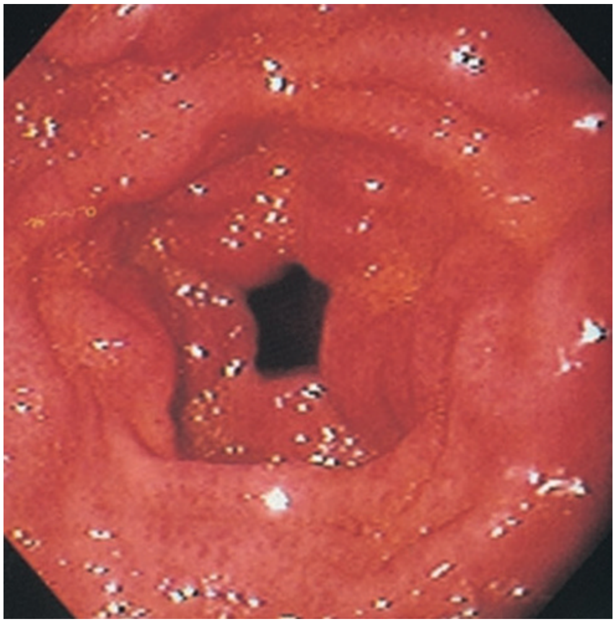

Figure 26.49 Endoscopic appearance of acute GVHD in the stomach, day 32. The pyloric channel is in the center of the picture. The mucosa of the gastric antrum is edematous, reddened, and friable.

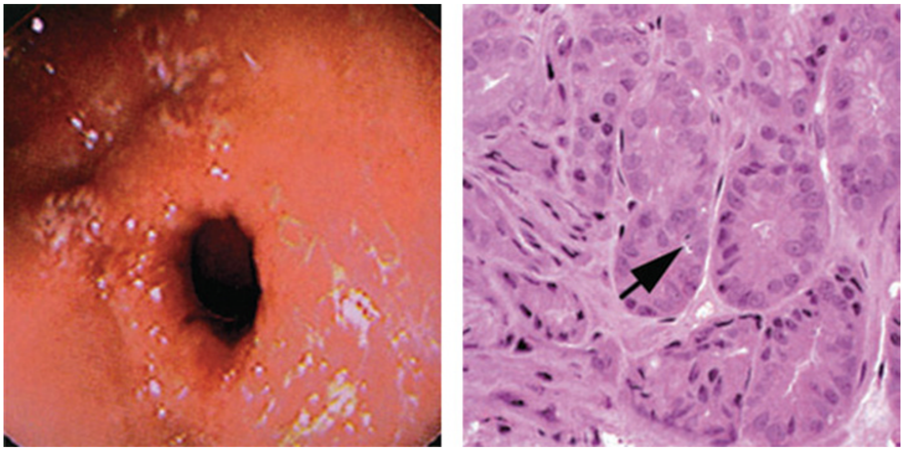

Figure 26.50 Gastric GVHD in which the severe mucosal erythema, edema, and erosion seen endoscopically on the left are more striking that the focal, mild, epithelial cell apoptosis (arrow) in the histological section on the right. Although a lymphocytic infiltrate is absent, apoptosis in multiple crypts is consistent with graft-versus-host activity. Inflammation may have been partially controlled by immunosuppressive therapy. Source: Ponec et al. 1999 [118]. Reproduced with permission of Elsevier.

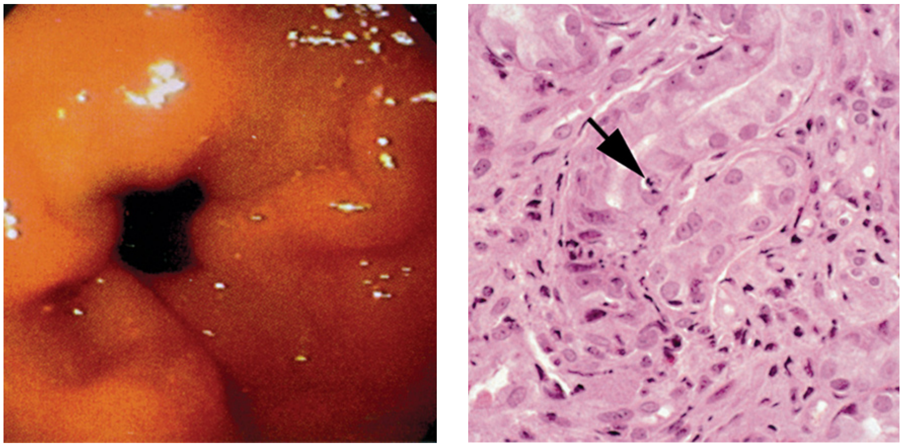

(a) (b)

Figure 26.51 Gastric GVHD in which the antral mucosa is endoscopically normal aside from edema (left). With air insufflation through the endoscope the antrum did not distend and there was no motor activity. Biopsy of such a bland area can be diagnostic. In this case, as shown in the photomicrograph on the right, there was epithelial cell apoptosis (arrow) and moderate lymphocytic infiltration diagnostic for GVHD. Source: Ponec et al. 1999 [118]. Reproduced with permission of Elsevier.

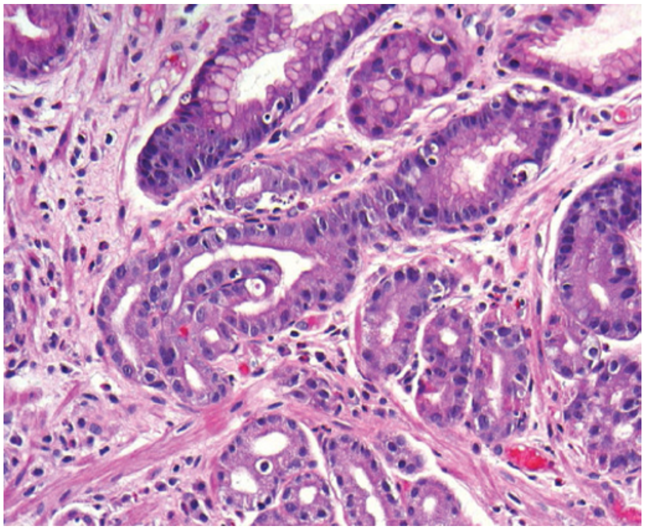

Figure 26.53 Gastric GVHD with architectural disarray and edematous antral mucosa. There are numerous intraepithelial lymphocytes infiltrating glands which also demonstrate reactive atypia. Apoptosis is widespread along with segmental disruption of the glands.

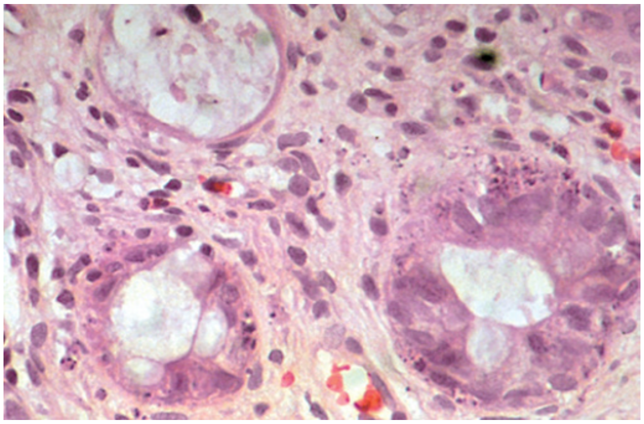

Figure 26.55 Rectal biopsy with GVHD, day 53. Three mucosal crypts display varying degrees of damage. The crypt on the right shows many apoptotic cells. More extensive cell damage is present in the crypt on the lower left. The upper crypt has lost all enterocytes. Note infiltrating lymphocytes in the lower left crypt associated with nuclear debris characteristic of apoptosis. Source: reproduced with permission of Dr. Robert C. Hackman.

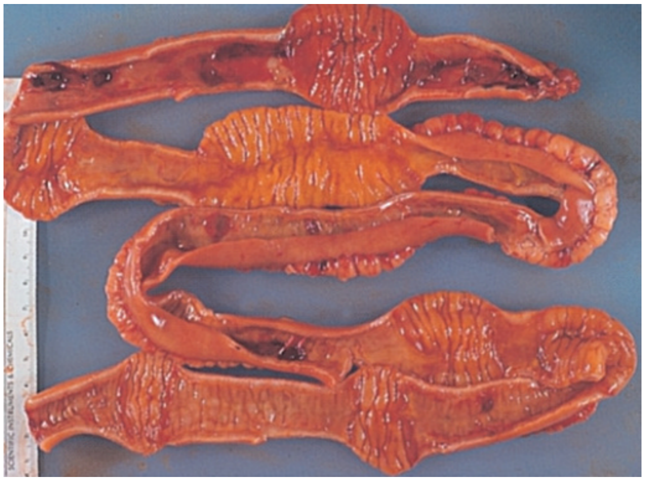

Figure 26.57 Surgical resection of severe long-standing intestinal GVHD, day 207. Scarred, ulcerated mucosa alternates with dilated areas of mucosal regeneration. The ulcerated portions demonstrate complete loss of epithelium and severe submucosal fibrosis. There is very high risk of invasive fungal or bacterial infection. Some patients have responded well to intestinal resection for localized GVHD.

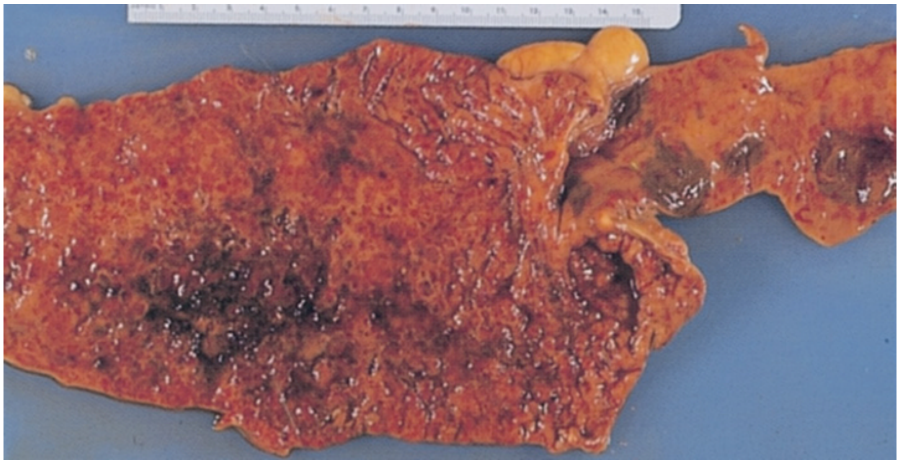

Figure 26.58 Severe GVHD of ileum and cecum, day 80. The mucosal lining and folds are replaced by a friable, beefy red, diffusely ulcerated lamina propria. The numerous exposed capillaries ooze blood and serum, a major cause of morbidity from intestinal GVHD. The endothelial cells and fibroblasts within the lamina propria are often infected with CMV, as was true in this patient.

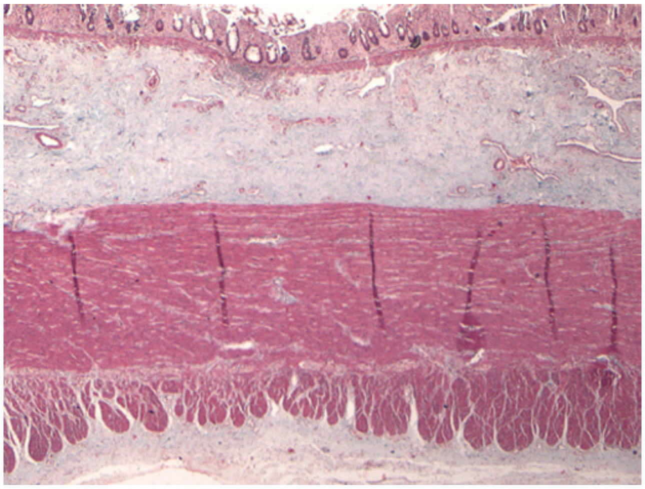

Figure 26.59 Collagenous colitis with long-standing refractory extensive chronic GVHD. The thickened bowel has extensive deposition of collagen in the submucosa, serosa as well the lamina propria.

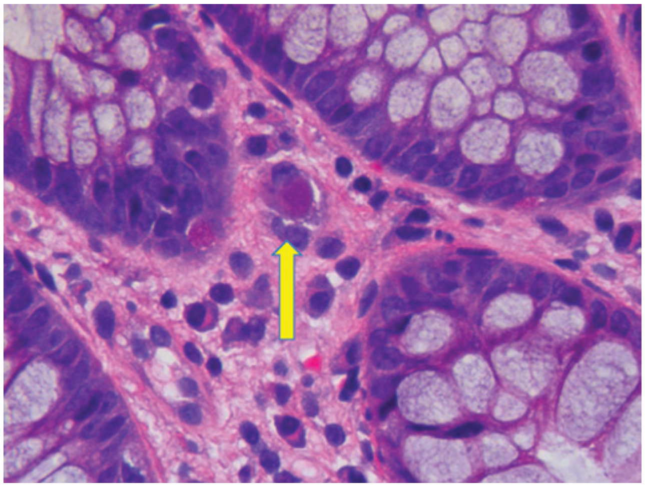

Figure 26.60 CMV infection in a patient with T-cell prolymphocytic leukemia from day 516 after HCT with chronic diarrhea. The yellow arrow indicates the classic large eosinophilic inclusion in a stromal cell.

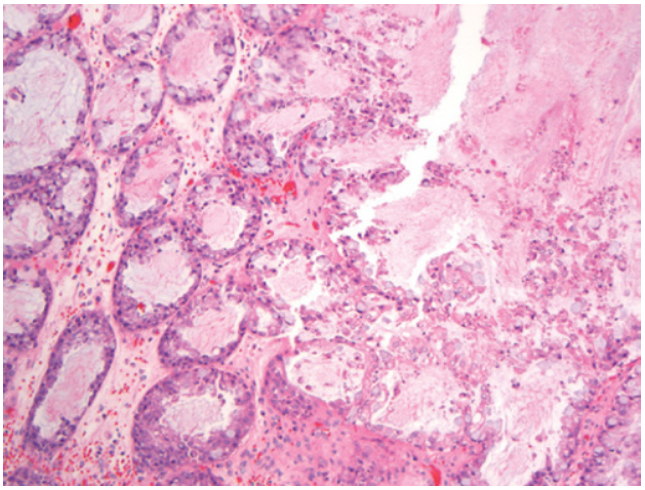

Figure 26.61 Fatal pseudomembranous colitis. An acute abdomen developed 15 days post-transplant. The degenerative colonic crypts were covered with a cap of mucin admixed with sloughed cellular debris containing large colonies of bacteria consistent with *Clostridium* sp.

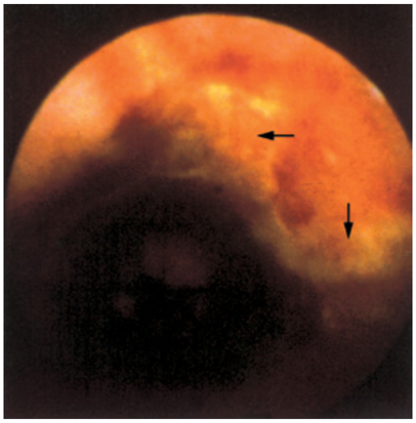

Figure 26.62 Endoscopic appearance of CMV esophagitis, day 61. A large, shallow ulcer with serpiginous, reddened borders is seen in the distal esophagus. The ulcer base (arrows) has a yellow, reticulated appearance.

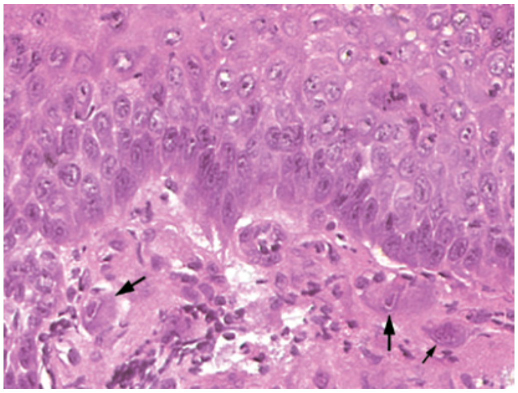

Figure 26.63 Esophageal biopsy showing CMV infection, day 61. Beneath the epithelium are two cytomegalic cells (large arrows), each containing a single, large, oval intranuclear inclusion surrounded by a clear halo (Cowdry type A). A third cell (small arrow) is probably also infected but is morphologically non-diagnostic. It would presumably be positive by immunocytochemistry and in situ hybridization techniques. Studies of cell morphology and also viral DNA and antigen expression indicate that the esophageal squamous epithelium is never infected with CMV.

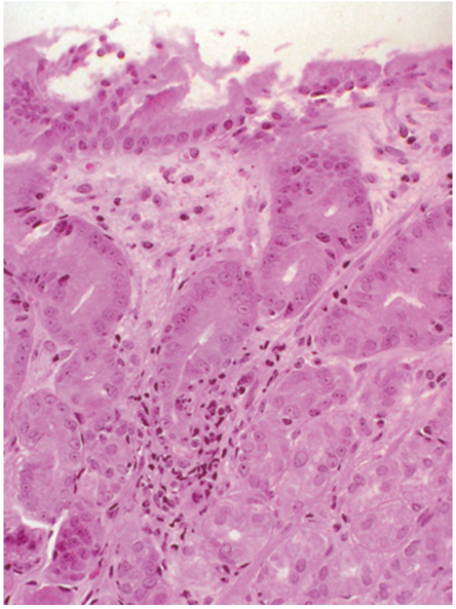

Figure 26.64 Autologous gastric GVHD or lymphocytic gastritis. The focal mononuclear inflammatory cell infiltration of the lamina propria and mucosal crypt associated with crypt epithelial cell apoptosis is histologically indistinguishable from GVHD in an allograft recipient. This inflammation may develop after autologous or syngeneic BMT if tolerance to self-MHC antigens is not re-established and autoreactive cells are allowed to persist.

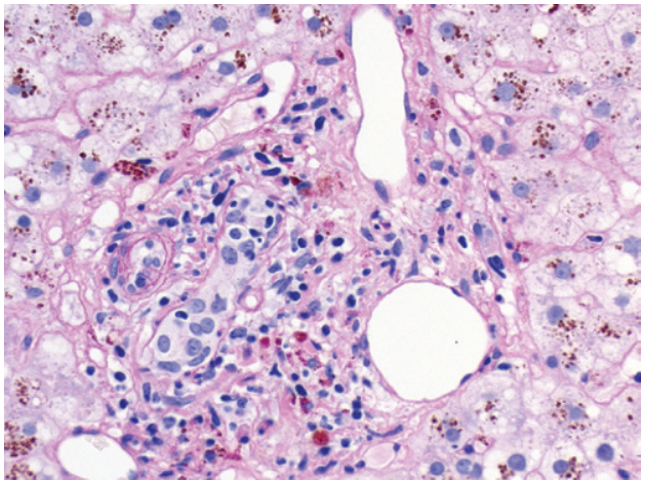

Figure 26.66 Hepatic GVHD. The PAS-stained section highlights a damaged interlobular bile duct that is infiltrated by lymphocytes. The nuclei vary in size and are irregularly arranged. The syncytium-like segment reflects nuclear loss.

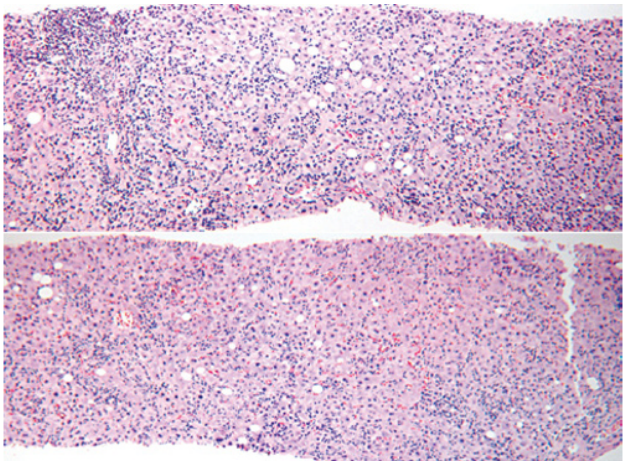

Figure 26.67 Acute hepatitic onset of GVHD at 10 months post-transplant. Three months after tapering off immunosuppression, the aminotransferases rose to 2000 u and alkaline phosphatase three times normal with normal bilirubin. This biopsy 1 was performed 26 days from the onset and shows an extensive lobular hepatitis with intense lymphocytic inflammation of sinusoids and portal spaces and hepatocellular necrosis.

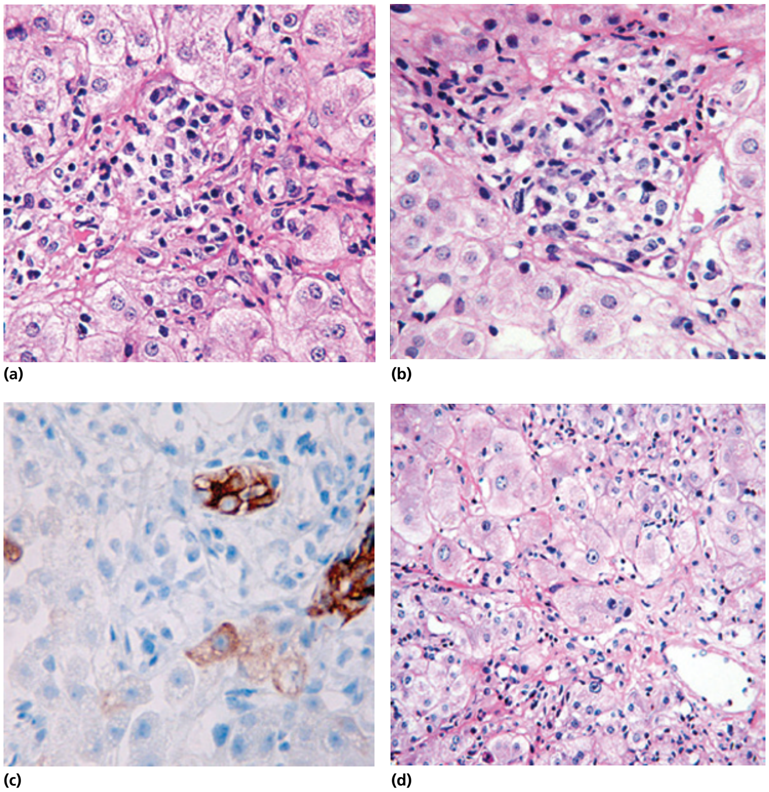

Figure 26.68 This biopsy 2 was done 1 month later (see Figure 26.67) when the total bilirubin was 30 mg/dL. Images (a) and (b) show a lymphoplasmacytic portal infiltrate which obscures the damaged interlobular bile ducts. In (c), immunostaining with cytokeratin 7 demonstrates that damaged bile ducts are still present. In (d), there is perivenular (zone 3) cholestasis. Hepatocytes show ballooning, and there is focal dropout associated with a patchy lymphocytic infiltrate. The patient made a full recovery after immunosuppressive treatment for GVHD was initiated.

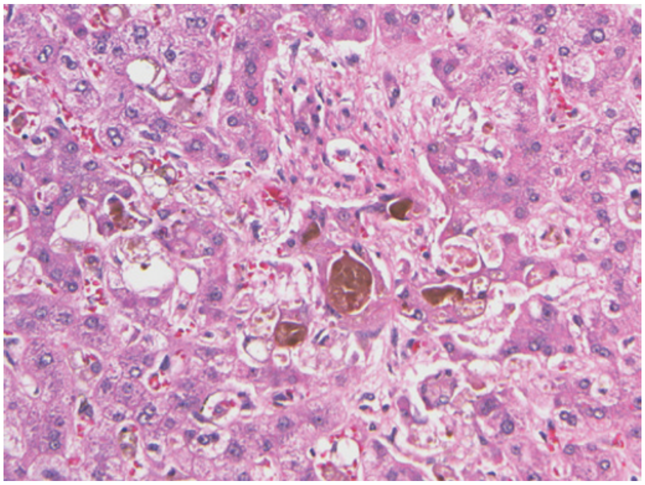

Figure 26.70 Hepatic GVHD with severe cholangitis lenta-like cholangiolar hepatocellular cholestasis. The interlobular bile duct is no longer recognizable. A ductular reaction with large bile-filled cholangioles lies along the periphery of the enlarged irregular portal space. The adjacent hepatocyte cords display marked unrest, disarray, and cytoplasmic ballooning.

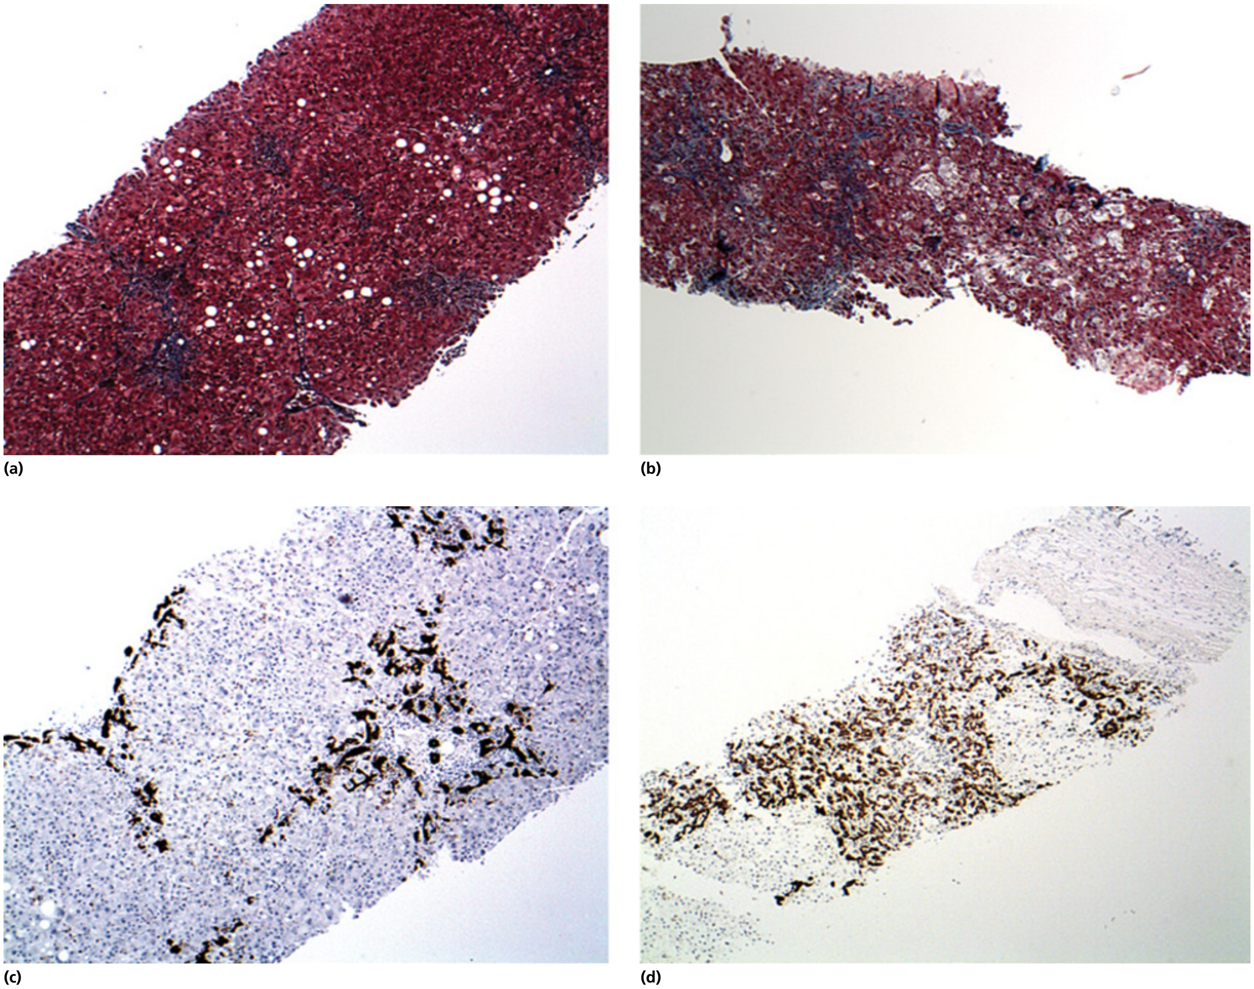

Figure 26.71 Rapidly evolving fibrosing cholestatic hepatitis C. Donor was positive for hepatitis C. Liver biopsies from day 70 [(a) and (c)] and day 88 [(b) and (d)] showing expanding portal fibrosis, hepatocyte necrosis and dropout, and marked bile ductule proliferation seen with cytokeratin 19 IHC [(c) and (d)].

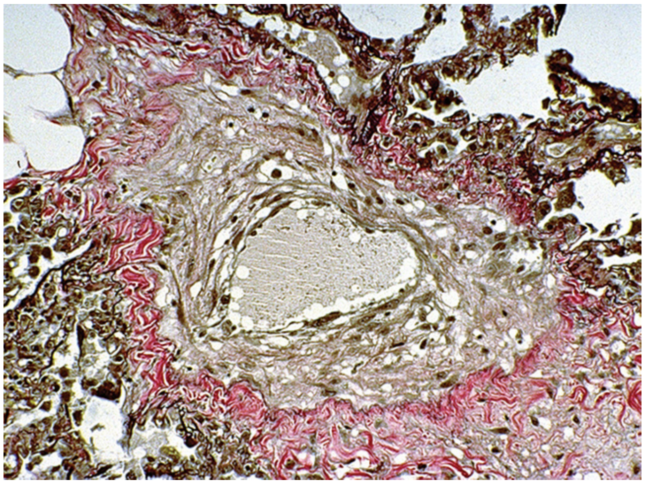

Figure 26.72 Pulmonary veno-occlusive disease (VOD) in a lung biopsy from a patient with pulmonary hypertension 48 days after second allogeneic BMT for acute lymphoblastic leukemia. Loose intimal fibrosis partially occludes the interlobular vein. This complication probably results from chemotherapy and may be more frequent than previously suspected. (Verhoeff–van Gieson elastin stain.)

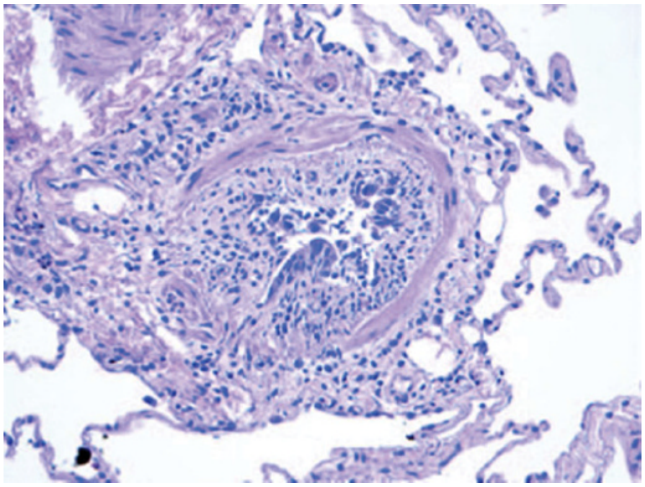

Figure 26.75 Bronchiolitis with evolving subepithelial fibrosis and lymphohistiocytic infiltration. There is marked epithelial damage. In this patient with chronic GVHD and obstructive pulmonary function abnormalities, the alterations are consistent with pulmonary GVHD. Similar changes could be seen in respiratory virus infection, which was absent in this biopsy. The ongoing inflammation and subtotal constrictive obliteration of this airway suggest that immunosuppressive therapy may be beneficial.

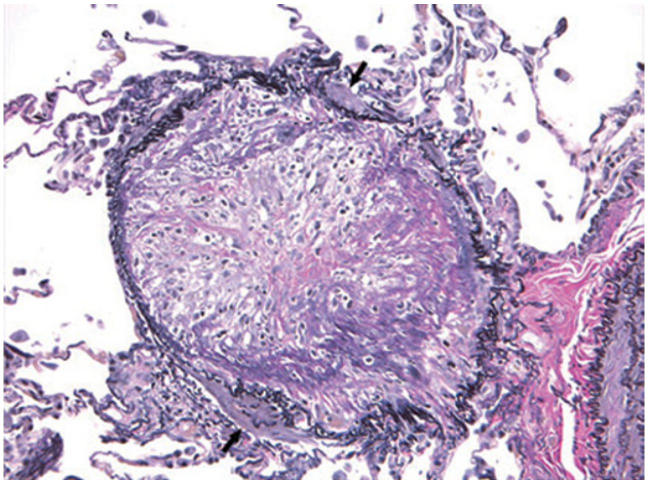

Figure 26.76 In a patient with a history similar to the preceding case (see Figure 26.75), the bronchiolitis obliterans of chronic pulmonary GVHD has progressed. This bronchiole is completely occluded by granulation tissue, and scattered mononuclear inflammatory cells are present. Without successful intervention with immunosuppressive therapy, this airway will finally probably be replaced by permanent scar tissue. The arrows indicate residual smooth muscle. The elastin fibers are black with this Verhoeff–van Gieson stain.

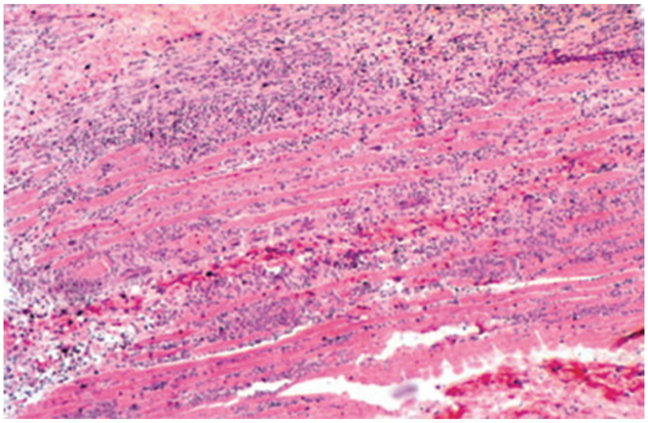

Figure 26.77 Polymyositis in deltoid muscle biopsy associated with chronic GVHD, day 1129. There is extensive endomysial chronic inflammation associated with myocyte destruction. The condition responded to immunosuppressive therapy.

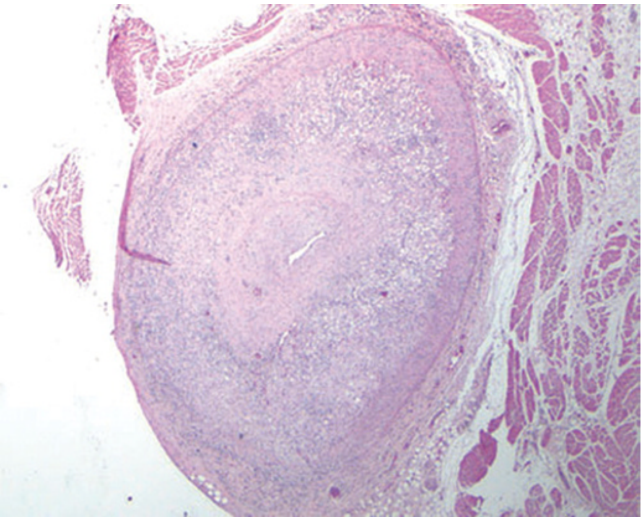

Figure 26.78 Coronary arteriopathy associated with chronic GVHD in a 15-year-old who died of myocardial infarction preceded by severe anginal symptoms. The lumen and muscular wall of all the major coronary arteries were subtotally to completely obliterated by a cellular infiltrate of lymphoid and monocytoid cells admixed with extracellular matrix.

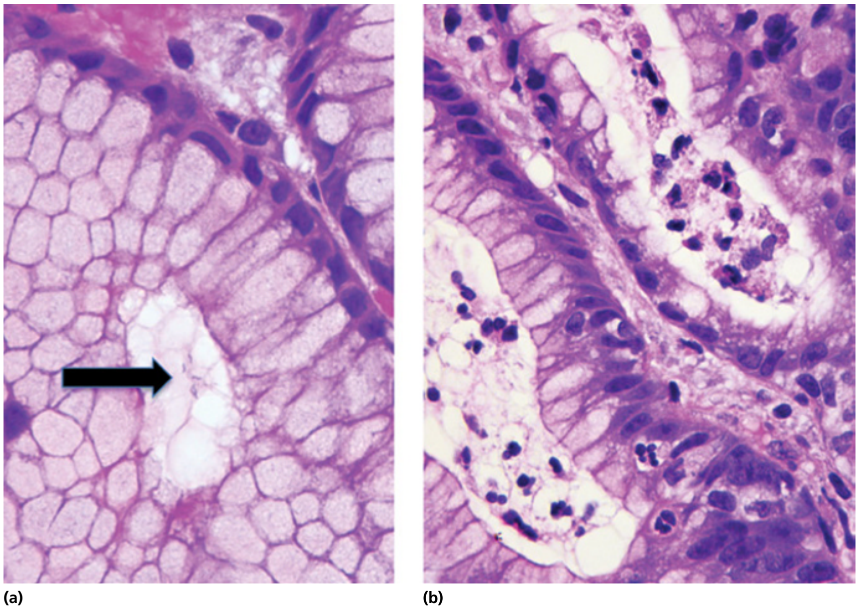

Figure 26.79 Gastric biopsy stained with H&E in a patient with chronic myeloid leukemia, day 37 post-HCT with persistent nausea and erythematous gastric lining by endoscopy non-responsive to steroids. (a) Gastric glands with a group of *Helicobacter pylori* organisms (black arrow) confirmed by immunohistochemistry. (b) Adjacent glands showing acute inflammation and a few *H. pylori* organisms.

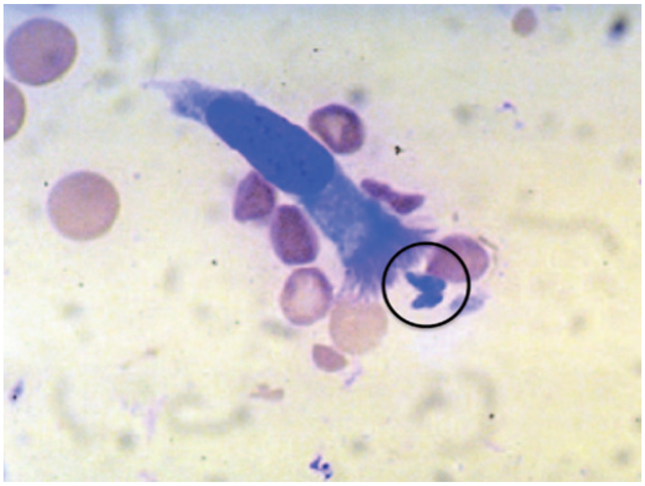

Figure 26.80 Two *Toxoplasma* tachyzoites (inside the circle) are present near the ciliated surface of a bronchial epithelial cell. Diagnosis of *Toxoplasma* pneumonia was established in less than 2 hours after bronchoalveolar lavage. Wright–Giemsa stain of cytospin preparation.

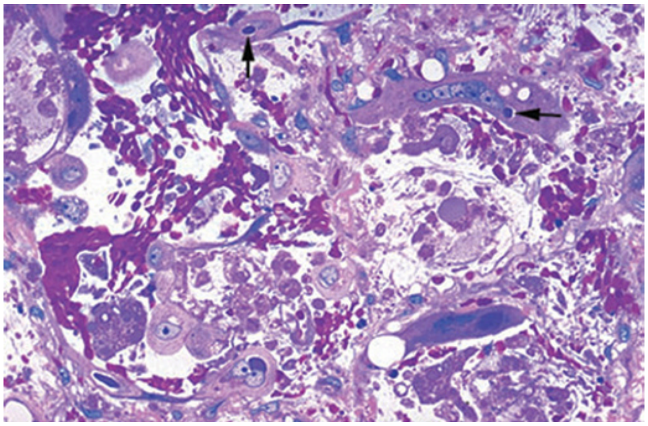

Figure 26.83 Respiratory syncytial virus (RSV) pneumonia in a lung biopsy, day 48. The presence of dark purple cytoplasmic inclusions in multinucleated epithelial cells (arrows) suggests the diagnosis but may be found with other viruses such as parainfluenza. During severe community outbreaks, infections may spread to hospitalized marrow recipients.

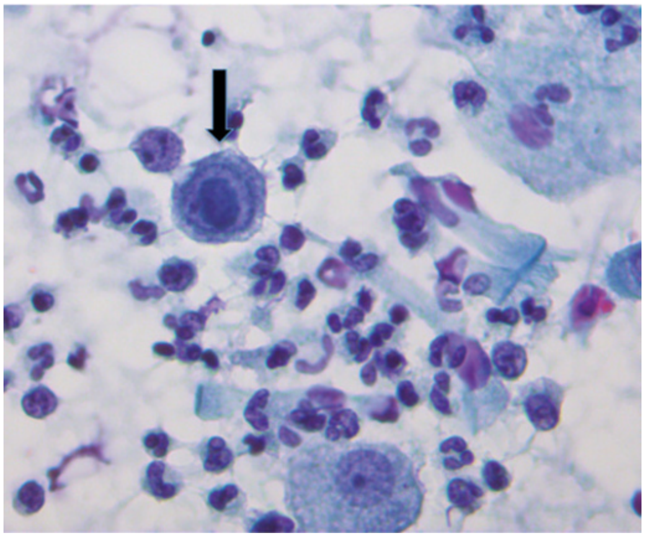

Figure 26.82 Cytomegalovirus cytopathic changes seen in a cytospin preparation of a bronchoalveolar lavage in a patient with B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma. Among a neutrophilic background is an infected alveolar macrophage (arrow) which demonstrates some cytoplasmic inclusion and a markedly enlarged nuclei with a single prominent enlarged central nucleoli. There is a relatively normal alveolar macrophage at the bottom middle of the picture for comparison.

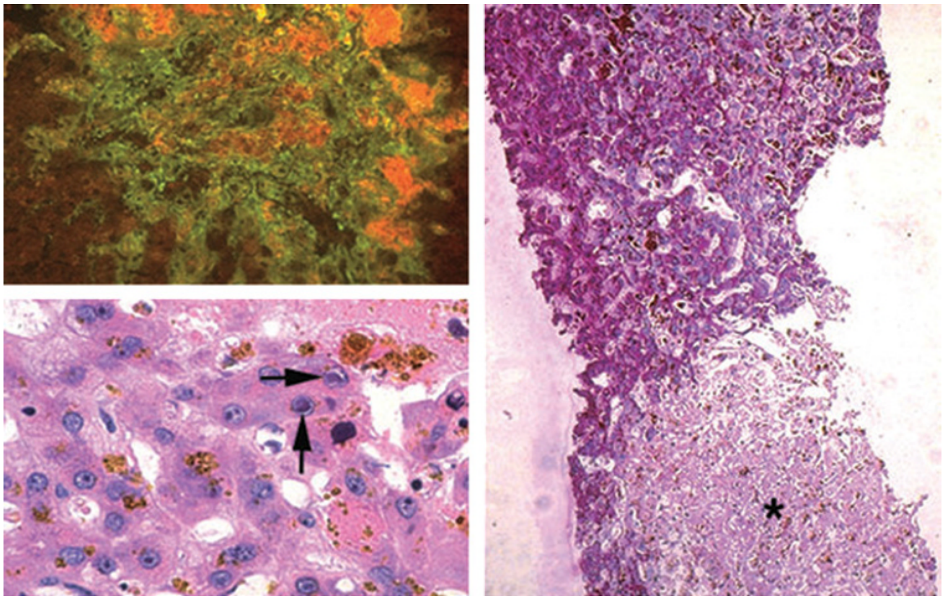

Figure 26.84 Varicella zoster virus (VZV) hepatitis in a percutaneous needle biopsy, day 79. On the right, a PAS stain demonstrates a pale necrotic area (*) bordered by cells containing nuclear inclusions (large arrows) visible by H&E stain on the lower left. Immunofluorescence confirmed the presence of VZV (upper left), and intravenous acyclovir was begun within hours of the biopsy.

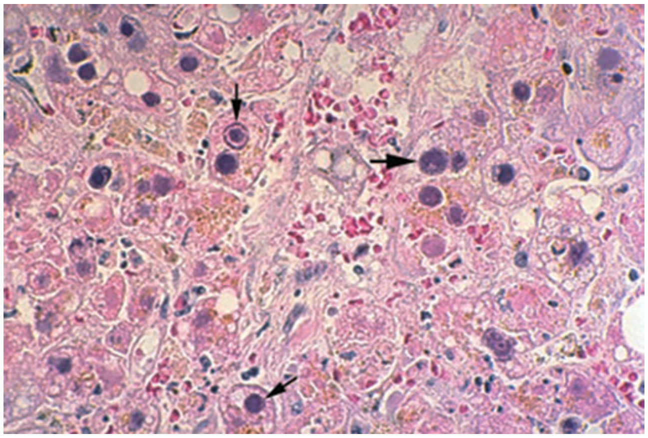

Figure 26.85 Overwhelming adenovirus hepatitis at autopsy 92 days after allogeneic BMT for AML. Dark basophilic nuclear inclusions produce "smudge cells" (large arrows) with blurred nuclear margins. Occasional cells with a halo around the inclusion (small arrow) suggest a combined infection with CMV, which was confirmed by isolation of both viruses.

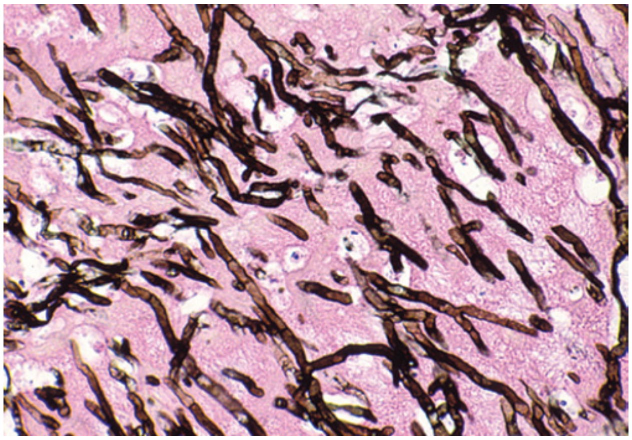

Figure 26.87 Mahan's methenamine silver stain of a lung biopsy showing a central necrotic cavity with infiltration by septate fungal 45° branching hyphae morphologically consistent with *Aspergillus*, which was subsequently confirmed with PCR. Source: reproduced with permission of Dr. Robert C. Hackman.

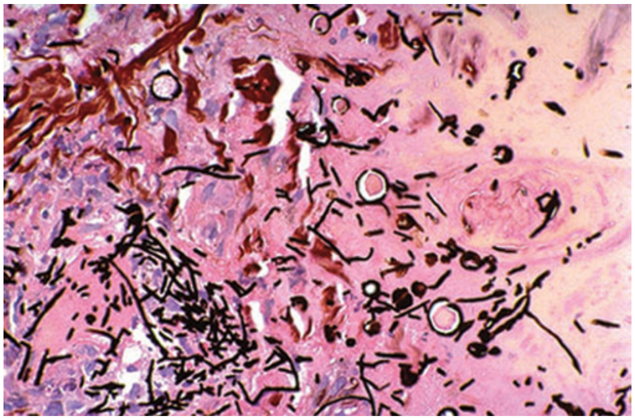

Figure 26.88 Mahan's methenamine silver stain showing that *Fusarium* hyphae invade the dermis in pre-transplant skin biopsy.

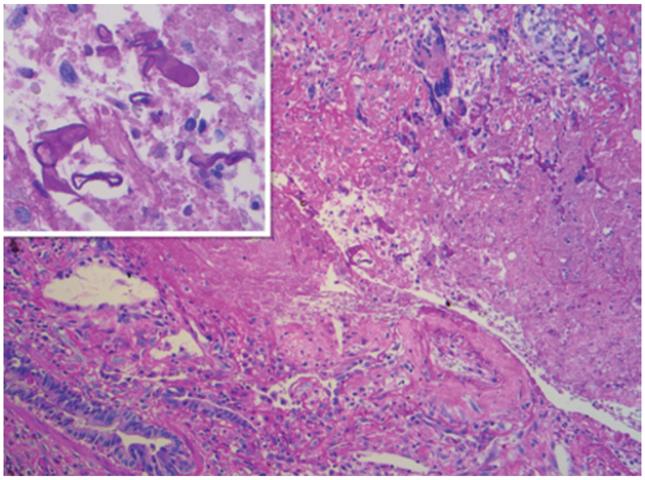

Figure 26.89 Lung biopsy specimen stained with PAS treated with diastase demonstrates Zygomycetes infection in a patient with sickle cell disease day 294 after HCT. There is extensive necrosis and giant cell reaction associated with the fungal organisms. Ribbon-like haphazardly arranged fungal hyphae are shown at high power in the inset.

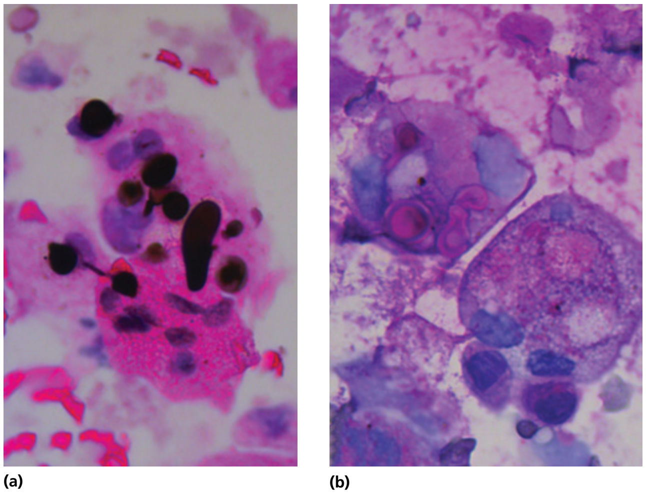

Figure 26.90 (a) A cytospin preparation of a bronchoalveolar lavage stained with Mahan's methenamine silver showing intracellular fungal organisms in an alveolar macrophage, later shown to be *Candida albicans* by fungal culture. (b) Same specimen stained with PAS showing the same intracellular *C. albicans* organism including a budding yeast form.

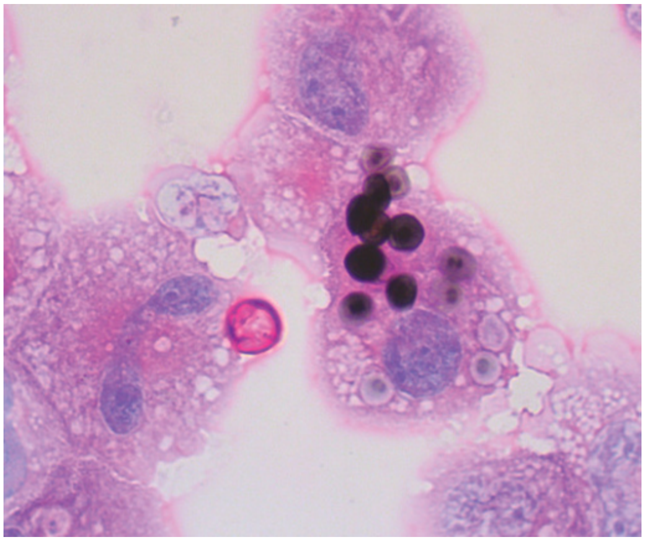

Figure 26.91 A cytospin preparation of a bronchoalveolar lavage stained with Mahan's methenamine silver showing intracellular pneumocystis organisms in an alveolar macrophage.

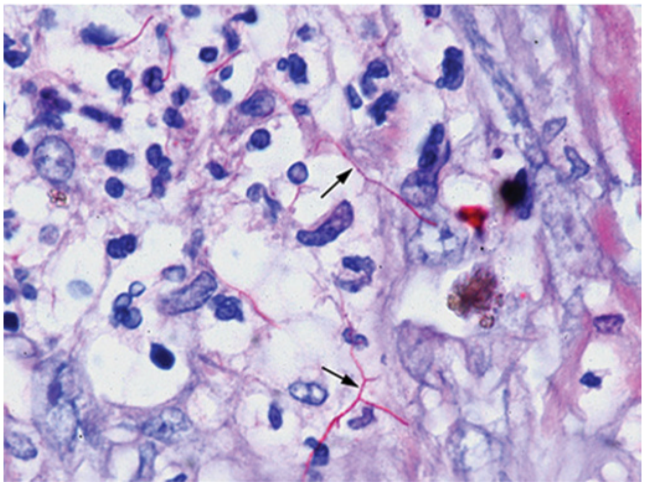

Figure 26.92 Fite stain of a lung biopsy showing thin filamentous branched *Nocardia* (arrow). Source: reproduced with permission of Dr. Robert C. Hackman.

Figure 40.2 Cartoon depicting normal and leukemic cell interactions with the marrow microenvironment. Source: Schroeder and DiPersio 2012 [18]. Reproduced with permission of Society of Leukocyte Biology and John Wiley & Sons Ltd.

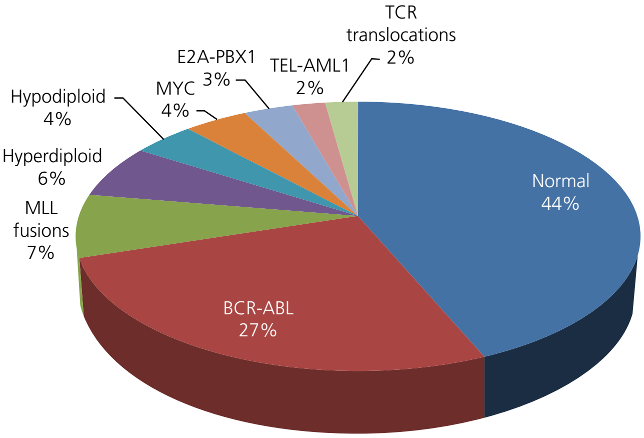

Figure 52.1 Frequency and distribution of cytogenetic abnormalities in adult patients with ALL. Dark blue includes normal cytogenetics (no recurrent chromosomal abnormalities), rust is **BCR-ABL** [t(9:22)], olive green is **MLL fusions** [t(4;11), t (1;11). T (11;19)], purple is hyperdiploid (>50 chromosomes), teal is hypodiploid (<45 chromosomes), orange is **MYC** [Ig translocations t(8;14), t(2;8), t(8;22)], light blue is **E2A-PBX1** [t(1;19)], pink is **TEL-AML1** [t(12;21)], and light green is **TCR translocations** (7q35/TCRβ, 14q1/TCRαδ), where the genes affected by chromosomal translocations are shown in bold face. Source: adapted and redrawn from Gutierrez et al. 2009 [1].

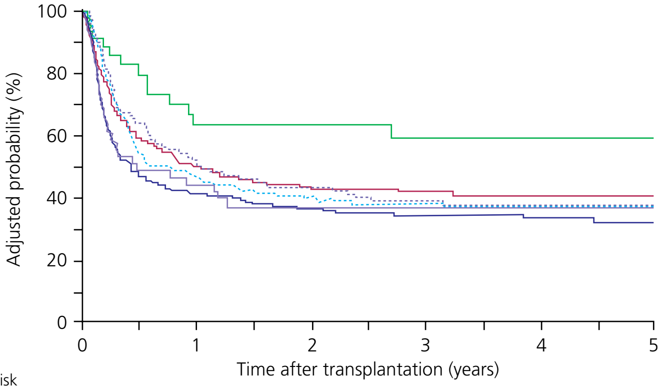

Numbers at risk		0	1	2	3	4	5
HLA-matched cord blood	—	35	20	17	13	11	8
HLA-matched bone marrow	⋯	116	62	45	35	29	24
One-mismatched cord blood (high cell dose)	—	157	72	55	44	32	25
HLA-mismatched bone marrow	⋯	166	77	60	53	44	30
One-mismatched cord blood (low cell dose)	—	44	19	13	12	10	6
Two-mismatched cord blood	—	267	100	67	49	34	21

Figure 53.4 Probability of leukemia-free survival after BM and UCB transplantation adjusted for disease status at transplantation.

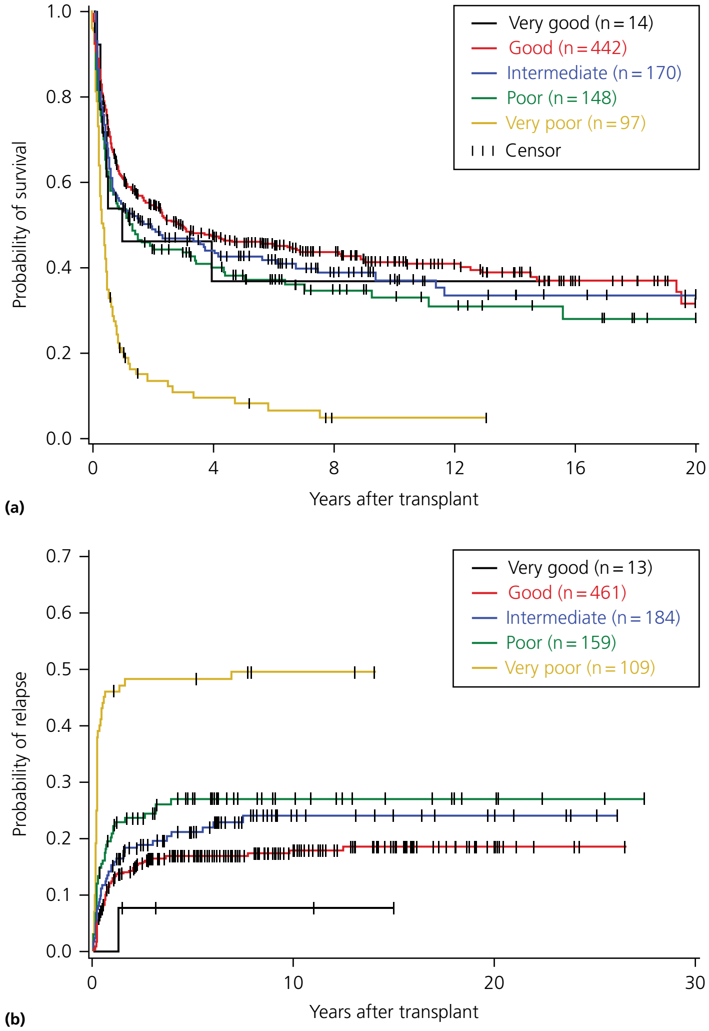

Figure 54.1 Impact of the five-group cytogenetic risk classification (incorporated into the IPSSR) [7,29] on transplant outcome. (a) Surivival. (b) Cumulative incidence of relapse. +, Censored patient.

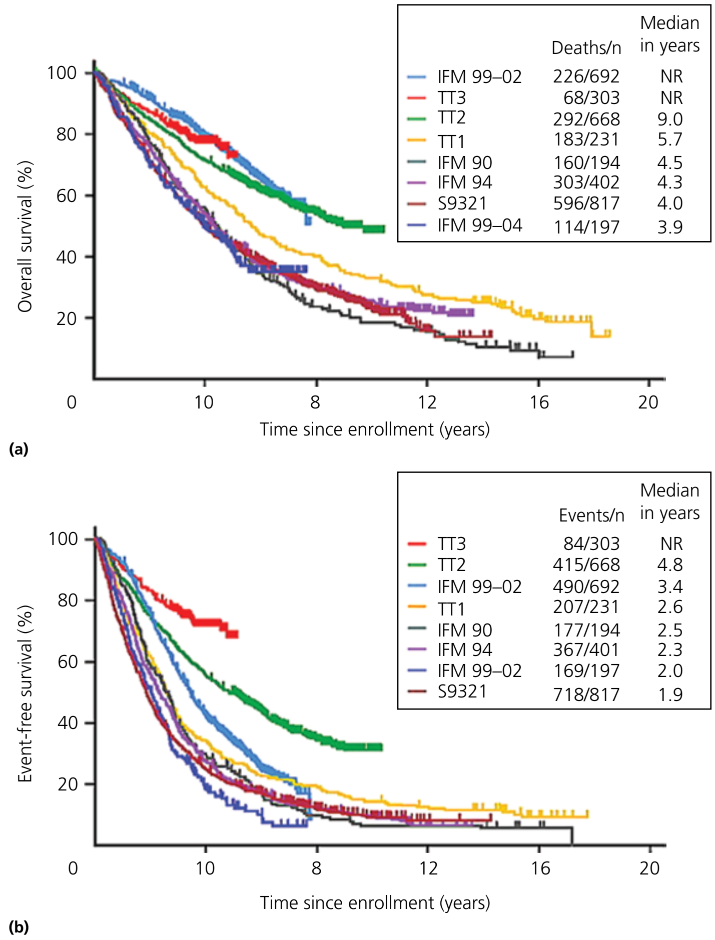

Figure 55.1 Long-term outcomes of large prospective autologous SCT trials. Source: Barlogie et al. 2010 [106]. Reproduced with permission of the American Society of Clinical Oncology.

Index

Abbreviations used: ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; CMML, juvenile (chronic) myelomonocytic leukemia *and* chronic myelomonocytic leukemia; GI, gastrointestinal; GVHD, graft-versus-host disease; GVL, graft-versus-leukemia effect; GVT response, graft-versus-tumor response; HC, hematopoietic cell; HD, Hodgkin disease; HCT, hematopoietic cell transplantation; HPC, hematopoietic progenitor cells; HSC, hematopoietic stem cell; HSPC; hematopoietic stem and progenitor cell; JMML, juvenile myelomonocytic leukemia; mAb, monoclonal antibody; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasms; MSC, mesenchymal stem cell; NHL, non-Hodgkin lymphoma; PBHC, peripheral blood hematopoietic cells; PBHCT, peripheral blood hematopoietic cell transplantation; PBPC, peripheral blood progenitor cells; PBSC, peripheral blood stem cells; PTLD, post-transplant lymphoproliferative disorder; QoL, quality of life; TBI, total body irradiation.

Thomas' Hematopoietic Cell Transplantation

This book is dedicated to our patients and their families whose courage and trust enabled them to choose a difficult, dangerous, and sometimes unproven therapy which offered the only chance in their fight against a fatal disease. Today, many thousands of patients are alive after a successful hematopoietic cell transplantation, which would have been impossible without the fortitude of our patients, who took risks and thereby paved the way for the increasing application of this therapy. The progress in the area of clinical transplantation of hematopoietic cells would not have been possible without the dedicated, tireless work of the nurses and the supporting staff in the many transplant units around the world.

Thomas' Hematopoietic Cell Transplantation

Stem Cell Transplantation

VOLUME II

Edited by

Stephen J. Forman, MD
Chair, Department of Hematology and Hematopoietic Cell Transplantation
City of Hope Comprehensive Cancer Center
Duarte, CA, USA

Robert S. Negrin, MD

Thomas' hematopoietic cell transplantation : stem cell transplantation / edited by Stephen J. Forman, Robert S. Negrin, Joseph H. Antin, Frederick R. Appelbaum. – Fifth edition.
p. ; cm.
Hematopoietic cell transplantation
Includes bibliographical references and index.
ISBN 978-1-118-41600-6 (cloth)
I. Forman, Stephen J., editor. II. Negrin, Robert S., editor. III. Antin, Joseph H., editor. IV. Appelbaum, Frederick R., editor.
V. Title: Hematopoietic cell transplantation.
[DNLM: 1. Hematopoietic Stem Cell Transplantation. 2. Transplantation Immunology. WH 380]
RD123.5
617.4′4–dc23
2015004071

A catalogue record for this book is available from the British Library.

Wiley also publishes its books in a variety of electronic formats. Some content that appears in print may not be available in electronic books.

This book comes with free access to a **Wiley Companion Digital Edition** powered by **VitalSource** providing a digital, interactive version of this book. Your Wiley Companion Digital Edition allows you to search, make notes and highlights, organize, clip figures, and link content.

To access your **Wiley Companion Digital Edition**
- Find the redemption code by carefully scratching away the top coating of the label found in the inside panel of the front cover of this book.
- Visit https://support.vitalsource.com for directions on how to first download the Vital Source Bookshelf to your device, computer or laptop, and then redeem your code. See support topic 'Getting Started with VitalSource Bookshelf'.

If you have purchased this title as an e-book, Wiley Customer Care will provide your access code for the online edition. Please visit http://support.wiley.com to request via the "Live Chat" or "Ask A Question" tabs within 90 days of purchase, and please have your receipt for verification.

Contents

Contributors, xi

Preface to the First Edition, xvii

Preface to the Fifth Edition, xviii

Tribute, xix

List of Abbreviations, xxii

VOLUME I

Section 1: History and Use of Hematopoietic Cell Transplantation

1 A History of Allogeneic and Autologous Hematopoietic Cell Transplantation, 1
Karl G. Blume and E. Donnall Thomas

2 Uses and Growth of Hematopoietic Cell Transplantation, 8
Mary M. Horowitz

Section 2: Scientific Basis or Hematopoietic Cell Transplantation

Section 2A: Hematopoiesis and Stem Biology Transplantation

3 Generation of Definitive Engraftable Hematopoietic Stem Cells from Human Pluripotent Stem Cells, 16
Laurence Dahéron and David T. Scadden

4 Hematopoietic Stem Cells, Regenerative Medicine, and Leukemogenesis, 25
Irving Weissman

5 Marrow Microenvironment and Biology of Mobilization of Stem Cells, 50
Michael P. Rettig, Mark A. Schroeder and John F. DiPersio

6 Expansion of Human Hematopoietic Stem Cells, 62
Colleen Delaney

7 Mesenchymal Stromal Cells and Hematopoietic Cell Transplantation, 69
Edwin M. Horwitz

8 Genetic Manipulation of Hematopoietic Stem Cells, 78
Jennifer E. Adair, Grant D. Trobridge and Hans-Peter Kiem

Section 2B: Immunology

9 Overview of Hematopoietic Cell Transplantation Immunology, 96
Paul J. Martin and Warren D. Shlomchik

10 Histocompatibility, 112
Effie W. Petersdorf

11 Natural Killer Cells and Allogeneic Hematopoietic Cell Transplantation, 126
Michael R. Verneris and Jeffrey S. Miller

12 Mechanisms of Tolerance, 136
Defu Zeng and Samuel Strober

13 The Pathophysiology of Graft-versus-Host Disease, 146
James L.M. Ferrara and Joseph H. Antin

14 Immune Regulation in Hematopoietic Cell Transplantation, 153
Robert S. Negrin and Jerome Ritz

15 Immune Reconstitution Following Hematopoietic Cell Transplantation, 160
Jarrod A. Dudakov, Miguel-Angel Perales and Marcel R.M. van den Brink

16 Biology of the Human Graft-versus-Tumor Response and How to Exploit It, 166
Edus H. Warren

17 Dendritic Cells in Hematopoietic Cell Transplantation, 178
Miriam Merad and Edgar G. Engleman

18 The Experimental Basis for Hematopoietic Cell Transplantation for Autoimmune Diseases, 191
Judith A. Shizuru

Section 2C: Technical Aspects

19 Pharmacologic Basis for High-dose Chemotherapy, 211
Borje S. Andersson, Benigno C. Valdez and Roy B. Jones

20 High-dose Preparatory Regimens, 223
William I. Bensinger

21 Reduced-intensity Allogeneic Transplantation Regimens, 232
Brenda M. Sandmaier and Rainer Storb

22 Radiotherapeutic Principles of Hematopoietic Cell Transplantation, 244
Jeffrey Y.C. Wong and Timothy Schultheiss

23 Radioimmunotherapy and Hematopoietic Cell Transplantation, 258
John M. Pagel and Ajay K. Gopal

24 Documentation of Engraftment and Characterization of Chimerism After Hematopoietic Cell Transplantation, 272
Paul J. Martin

25 The Detection and Significance of Minimal Residual Disease, 281
Merav Bar and Jerald P. Radich

26 Pathology of Hematopoietic Cell Transplantation, 292
Keith R. Loeb, Cecilia C. Yeung and Howard M. Shulman

27 Biostatistical Methods in Hematopoietic Cell Transplantation, 329
Joycelynne M. Palmer and Ted A. Gooley

28 Outcomes Research in Hematopoietic Cell Transplantation, 341
Stephanie J. Lee

Section 3: Patient-oriented Issues in Hematopoietic Cell Transplantation

29 The Evaluation and Counseling of Candidates for Hematopoietic Cell Transplantation, 349
Bart L. Scott and Brenda M. Sandmaier

30 Nursing Role in Hematopoietic Cell Transplantation, 362
Rosemary C. Ford, Mihkaila M. Wickline and Diane Heye

31 Ethical Issues in Hematopoietic Cell Transplantation, 374
David S. Snyder

32 Psychosocial Issues in Hematopoietic Cell Transplantation, 384
Richard P. McQuellon and Katharine E. Duckworth

33 Assessment of Quality of Life in Hematopoietic Cell Transplantation Recipients, 392
Karen L. Syrjala and Samantha Burns Artherholt

34 Sexuality Following Hematopoietic Cell Transplantation, 399
D. Kathryn Tierney

35 Hematopoietic Cell Transplantation: The Patient's Perspective, 407
Susan K. Stewart

Section 4: Sources of Hematopoietic Cell for Hematopoietic Cell Transplantation

36 Hematopoietic Cell Procurement, Processing, and Transplantation: Standards, Accreditation, and Regulation, 414
Phyllis I. Warkentin and Elizabeth J. Shpall

37 Bone Marrow and Peripheral Blood Cell Donors and Donor Registries, 423
Dennis L. Confer, John P. Miller and Jeffrey W. Chell

38 The Role of the Transplant Program in a Nuclear Accident or Terrorism, 431
Nelson J. Chao and Dennis L. Confer

39 Cord Blood Hematopoietic Cell Transplantation, 437
Hal E. Broxmeyer, Sherif S. Farag and Vanderson Rocha

40 Mobilization of Peripheral Blood Hematopoietic Cells for Autologous HCT, 452
Thomas C. Shea and John F. DiPersio

41 Peripheral Blood Hematopoietic Cells for Allogeneic Transplantation, 460
Norbert Schmitz and Peter Dreger

42 Cryopreservation of Hematopoietic Cells, 469
Scott D. Rowley

43 Use of Recombinant Growth Factors after Hematopoietic Cell Transplantation, 480
Jürgen Finke and Roland Mertelsmann

44 Hematopoietic Cell Transplantation from Human Leukocyte Antigen Partially Matched Related Donors, 489
Claudio Anasetti, Franco Aversa and Andrea Velardi

45 Hematopoietic Cell Transplantation from Unrelated Donors, 505
Effie W. Petersdorf

Section 5: Hematopoietic Cell Transplantation for Acquired Disease

46 Hematopoietic Cell Transplantation for Aplastic Anemia, 517
George E. Georges and Rainer Storb

47 Hematopoietic Cell Transplantation for Paroxysmal Nocturnal Hemoglobinuria, 537
Ryotaro Nakamura

48 Hematopoietic Stem Cell Transplantation for Chronic Myeloid Leukemia, 545
Jerald P. Radich and Ravi Bhatia

49 Hematopoietic Cell Transplantation for Juvenile Myelomonocytic Leukemia, 554
Charlotte M. Niemeyer and Franco Locatelli

50 Hematopoietic Cell Transplantation for Adult Acute Myeloid Leukemia, 563
Frederick R. Appelbaum

51 Hematopoietic Cell Transplantation for Childhood Acute Myeloid Leukemia, 576
Michael A. Pulsipher, Meghann McManus and Soheil Meshinchi

52 Hematopoietic Cell Transplantation for Acute Lymphoblastic Leukemia in Adults, 588
Stephen J. Forman

53 Hematopoietic Cell Transplantation for Acute Lymphoblastic Leukemia in Children, 600
Parinda A. Mehta and Stella M. Davies

54 Hematopoietic Cell Transplantation for Myelodysplastic Syndromes and Myeloproliferative Neoplasms, 613
H. Joachim Deeg

55 Hematopoietic Cell Transplantation for Multiple Myeloma, 625
Amrita Krishnan and Sergio A. Giralt

Index, 637

VOLUME II

56 Hematopoietic Cell Transplantation for Hodgkin Disease, 675
Philip J. Bierman and Auayporn Nademanee

57 Hematopoietic Cell Transplantation for Non-Hodgkin Lymphoma (B Cell), 692
Leslie L. Popplewell and Ginna G. Laport

58 Hematopoietic Cell Transplantation for Non-Hodgkin Lymphoma (T Cell), 703
Jasmine Zain and Sandra H. Thomas

59 Hematopoietic Cell Transplantation for Chronic Lymphocytic Leukemia, 714
Aaron C. Logan and David B. Miklos

60 Autologous Hematopoietic Cell Transplantation for Systemic Light Chain (AL-) Amyloidosis, 724
Heather J. Landau, Morie A. Gertz and Raymond L. Comenzo

61 Autologous Hematopoietic Cell Transplantation for Breast Cancer and Germ-cell Tumors, 739
Yago Nieto and Elizabeth J. Shpall

62 Hematopoietic Cell Transplantation for Renal Cell Carcinoma and Other Solid Tumors, 748
Richard W. Childs and Ramaprasad Srinivasan

63 Hematopoietic Cell Transplantation for Neuroblastoma, 760
Justin T. Wahlstrom and Katherine K. Matthay

64 Hematopoietic Cell Transplantation for Other Pediatric Solid Tumors, 768
Masanori Hayashi, David M. Loeb and Allen R. Chen

65 Hematopoietic Cell Therapy for Human Immunodeficiency Virus Infection, 781
Amrita Krishnan, Joseph Alvarnas, John J. Rossi and John A. Zaia

66 Hematopoietic Cell Transplantation for Autoimmune Diseases, 792
Richard A. Nash

67 Hematopoietic Cell Transplantation for Rare Hematologic Malignancies, 804
Vinod Pullarkat and Stephen J. Forman

68 Adoptive T-cell Therapy for Viral Disease in the Setting of Hematopoietic Cell Transplantation, 816
Catherine M. Bollard and Helen E. Heslop

69 Adoptive T-cell Therapy for Malignancy in the Setting of Hematopoietic Cell Transplantation, 826
Stephen J. Forman, Michael Kalos and Carl H. June

70 Relapse of Hematologic Malignancy After Allogeneic Hematopoietic Transplantation, 836
Richard Champlin

Section 6: Hematopoietic Cell Transplantation for Inherited Disease

71 Hematopoietic Cell Transplantation for Thalassemia, 842
Guido Lucarelli and Javid Gaziev

72 Hematopoietic Cell Transplantation for Sickle Cell Disease, 853
Mark C. Walters

73 Hematopoietic Cell Transplantation for Immunodeficiency Diseases, 866
Richard J. O'Reilly and Wilhelm Friedrich

74 Hematopoietic Cell Transplantation for Storage Diseases, 885
Joseph Rosenthal

75 Hematopoietic Cell Transplantation for Macrophage, Granulocyte and Osteoclast Disorders, 910
Rajni Agarwal

76 Hematopoietic Cell Transplantation for Fanconi Anemia, 923
John E. Wagner, Jakub Tolar, Arleen D. Auerbach and Margaret L. MacMillan

Section 7: Complications of Hematopoietic Cell Transplantation

77 Mechanisms and Treatment of Graft Failure, 944
Robert Lowsky and Hans Messner

78 Blood Group Incompatibilities and Hemolytic Complications of Hematopoietic Cell Transplantation, 955
Margaret R. O'Donnell

79 Principles of Transfusion Support Before and After Hematopoietic Cell Transplantation, 961
Jeffrey McCullough

80 Vascular Access and Complications, 976
I. Benjamin Paz

81 Pharmacologic Prevention of Acute Graft-versus-Host Disease, 990
Nelson J. Chao

82 T-cell Depletion to Prevent Graft-versus-Host Disease, 1004
Robert J. Soiffer

83 Manifestations and Treatment of Acute Graft-versus-Host Disease, 1012
Corey Cutler and Joseph H. Antin

84 Chronic Graft-versus-Host Disease – Clinical Manifestations and Therapy, 1020
Paul A. Carpenter, Mary E.D. Flowers and Steven Z. Pavletic

85 Bacterial Infections, 1038
Helen L. Leather and John R. Wingard

86 Fungal Infections After Hematopoietic Cell Transplantation, 1057
Kieren A. Marr

87 Cytomegalovirus Infection, 1069
John A. Zaia

88 Herpes Simplex Virus Infections, 1078
Sanjeet S. Dadwal and James I. Ito

89 Varicella Zoster Virus Infections, 1085
Dora Y. Ho and Ann M. Arvin

90 Epstein–Barr Virus Infection, 1105
Jennifer A. Kanakry and Richard F. Ambinder

91 Respiratory Viruses After Hematopoietic Cell Transplantation, 1112
Sachiko Seo and Michael Boeckh

92 HHV-6A, HHV-6B, HHV-7, and HHV-8 After Hematopoietic Cell Transplantation, 1122
Per Ljungman, Tetsushi Yoshikawa and Katherine N. Ward

93 Human Adenovirus, Polyomavirus, and Parvovirus Infections in Patients Undergoing Hematopoietic Stem Cell Transplantation, 1129
Hans H. Hirsch and Steven A. Pergam

94 Gastrointestinal and Hepatic Complications, 1140
David M. Hockenbery, Simone I. Strasser and George B. McDonald

95 Lung Injury Following Hematopoietic Cell Transplantation, 1156
Kenneth R. Cooke and Gregory A. Yanik

96 Kidney and Bladder Complications of Hematopoietic Cell Transplantation, 1170
Sangeeta Hingorani

97 Endocrine Complications Following Hematopoietic Cell Transplantation, 1181
Fouad R. Kandeel and Behrouz Salehian

98 Common Potential Drug Interactions Following Hematopoietic Cell Transplantation, 1206
Anne Poon and Lowan K. Ly

99 Nutrition Support of the Hematopoietic Cell Transplant Recipient, 1216
Paula Charuhas Macris and Kerry K. McMillen

100 Pain Management, 1225
Noelle V. Frey and Jonathan R. Gavrin

101 Oral Complications of Hematopoietic Cell Transplantation, 1242
Mark M. Schubert, Maria Elvira Pizzigatti Correa and Douglas E. Peterson

102 Growth and Development After Hematopoietic Cell Transplantation, 1257
K. Scott Baker and Anna Petryk

103 Delayed Non-malignant Complications After Hematopoietic Cell Transplantation, 1266
Smita Bhatia

104 Subsequent Malignant Neoplasms After Hematopoietic Cell Transplantation, 1275
Smita Bhatia and Ravi Bhatia

105 Neurologic Complications of Hematopoietic Cell Transplantation, 1287
Harry Openshaw and Bihong T. Chen

106 Vaccination of Allogeneic and Autologous Hematopoietic Cell Recipients, 1297
Trudy N. Small

Index, 1305

Contributors

Jennifer E. Adair, PhD
Assistant Member,
Clinical Research Division,
Fred Hutchinson Cancer Research Center;
University of Washington School of Medicine,
Seattle, WA, USA

Rajni Agarwal, MD
Associate Professor of Pediatrics,
Division of Stem Cell Transplantation
and Regenerative Medicine,
Department of Pediatrics,
Stanford University School of Medicine,
Stanford, CA, USA

Joseph Alvarnas, MD
Director of Medical Quality,
Department Hematology/HCT,
City of Hope Medical Center,
Duarte, CA, USA

Richard F. Ambinder, MD, PhD
Professor in the Departments of Oncology,
Pathology, Pharmacology, and Medicine,
Johns Hopkins School of Medicine,
Baltimore, MD, USA

Claudio Anasetti, MD
Senior Member and Chair,
Department of Blood and Marrow Transplantation,
Moffitt Cancer Center,
Tampa, FL, USA

Borje S. Andersson, MD, PhD
Professor of Medicine,
Department of Stem Cell Transplantation
and Cellular Therapy,
The University of Texas M.D.
Anderson Cancer Center, Houston, TX, USA

Joseph H. Antin, MD
Professor of Medicine,
Harvard Medical School;
Chief, Stem Cell Transplantation,
Dana-Farber Cancer Institute,
Brigham and Women's Hospital, Boston, MA, USA

Frederick R. Appelbaum, MD
Member and Director,
Clinical Research Division, Fred Hutchinson Cancer
Research Center;
Professor and Head,
Division of Medical Oncology,
University of Washington School of Medicine,
Seattle, WA, USA

Samantha Burns Artherholt, PhD
Acting Assistant Professor,
Department of Psychiatry and Behavioral Sciences,
University of Washington School of Medicine,
Seattle, WA, USA

Ann M. Arvin, MD
Professor of Pediatrics,
Microbiology, and Immunology,
Department of Pediatrics,
Division of Infectious Diseases,
Stanford University School of Medicine,
Stanford, CA, USA

Arleen D. Auerbach, PhD
Consultant,
Program in Human Genetics and Hematology,
The Rockefeller University,
New York, NY, USA

Franco Aversa, MD
Chair,
Hematology and BMT Unit,
Department of Clinical and Experimental Medicine,
University of Parma, Parma, Italy

K. Scott Baker, MD, MS
Director,
Pediatric Blood and Marrow Transplantation and
Survivorship Programs,
Clinical Research Division,
Fred Hutchinson Cancer Research Center,
Seattle, WA, USA

Merav Bar, MD
Assistant Member,
Clinical Research Division,
Fred Hutchinson Cancer Research Center,
Seattle, WA, USA

William I. Bensinger, MD
Member,
Fred Hutchinson Cancer Research Center;
Professor of Medicine, University of Washington
School of Medicine
Seattle, WA, USA

Ravi Bhatia, MD
Professor of Medicine,
Director, UAB Division of Hematology/Oncology,
Deputy Director, UAB Comprehensive Cancer Center,
University of Alabama at Birmingham,
Birmingham, AL, USA

Smita Bhatia, MD, MPH
Professor,
Department of Pediatrics;
Director of the Institute for Cancer Outcomes
and Survivorship,
School of Medicine;
Associate Director for Cancer Outcomes Research,
Comprehensive Cancer Center,
University of Alabama at Birmingham,
Birmingham, AL, USA

Philip J. Bierman, MD
Associate Professor,
University of Nebraska Medical Center,
Department of Internal Medicine,
Section of Oncology/Hematology,
Nebraska Medical Center, Omaha, NE, USA

Karl G. Blume, MD
Emeritus Professor of Medicine,
Stanford University School of Medicine,
Stanford, CA, USA

Michael Boeckh, MD
Member, Vaccine and Infectious Disease Division;
Member, Clinical Research Division;
Head, Infectious Disease Sciences Program,
Fred Hutchinson Cancer Research Center;
Professor, Department of Medicine,
University of Washington School of Medicine,
Seattle, WA, USA

Catherine M. Bollard, MBChB, MD
Professor of Pediatrics and Microbiology,
Immunology and Tropical Medicine,
The George Washington University,
School of Medicine and Health Sciences,
Children's National Health System,
Washington, DC, USA

Hal E. Broxmeyer, PhD
Distinguished Professor,
Department of Microbiology and Immunology,
Indiana University School of Medicine,
Indianapolis, IN, USA

Paul A. Carpenter, MB, BS
Member,
Clinical Research Division, Fred Hutchinson Cancer
Research Center;
Professor of Pediatrics,
Department of Pediatrics,
University of Washington School of Medicine,
Seattle, WA, USA

Richard Champlin, MD
Chairman,
Department of Stem Cell Transplantation and Cellular
Therapy;
Professor of Medicine,
Division of Cancer Medicine,
The University of Texas M.D.
Anderson Cancer Center, Houston, TX, USA

Nelson J. Chao, MD, MBA
Donald D. and Elizabeth G. Cooke Professor;
Chief, Division of Hematological Malignancies
and Cellular Therapy/BMT, Duke University,
Durham, NC, USA

Jeffrey W. Chell, MD
Chief Executive Officer,
National Marrow Donor Program,
Minneapolis, MN, USA

Allen R. Chen, MD, PhD, MHS
Associate Professor of Oncology and Pediatrics,
The Sidney Kimmel Comprehensive Cancer Center
at Johns Hopkins and Department of Pediatrics,
Johns Hopkins University School of Medicine,
Baltimore, MD, USA

Bihong T. Chen, MD, PhD
Associate Clinical Professor,
Department of Radiology,
City of Hope National Medical Center,
Duarte, CA, USA

Richard W. Childs, MD
Clinical Director,
NHLBI; Senior Investigator,
National Heart, Lung and Blood Institute,
National Institutes of Health, Bethesda, MD, USA

Raymond L. Comenzo, MD
Professor of Medicine and Pathology,
Tufts University School of Medicine; Attending
Physician and Director of the Transfusion Service
and the Cell Therapy Center,
Division of Hematology–Oncology,
Department of Medicine, Tufts Medical Center,
Boston, MA, USA

Dennis L. Confer, MD
Clinical Professor of Medicine,
Department of Medicine,
University of Minnesota; Chief Medical Officer,
National Marrow Donor Program,
Minneapolis, MN, USA

Kenneth R. Cooke, MD
Professor of Oncology and Pediatrics (PAR),
Division of Pediatric Hematology/Oncology,
Department of Oncology, Blood and Marrow
Transplant Program, Johns Hopkins University School
of Medicine, Baltimore, MD, USA

Maria Elvira Pizzigatti Correa, DDS, PhD
Professor of Oral Diagnosis,
Piracicaba School of Dentistry;
Dentist,
Hematology and Blood Transfusion Center,
Hemocentro, University of Campinas, UNICAMP,
Campinas, SP, Brazil

Corey Cutler, MD, MPH, FRCP(C)
Associate Professor of Medicine,
Harvard Medical School, Dana-Farber Cancer Institute,
Boston, MA, USA

Sanjeet S. Dadwal, MD
Associate Clinical Professor,
Division of Infectious Disease,
City of Hope National Medical Center,
Duarte, CA, USA

Laurence Dahéron, PhD
Head, iPS core facility,
Harvard Stem Cell Institute, Harvard University,
Boston, MA, USA

Stella M. Davies, MBBS, MRCP, PhD
Professor,
Division of Bone Marrow Transplantation and Immune
Deficiency, Cancer and Blood Diseases Institute,
Cincinnati Children's Hospital Medical Center,
Cincinnati, OH, USA

H. Joachim Deeg, MD
Professor of Medicine; Member,
Clinical Research Division, Fred Hutchinson Cancer
Research Center, University of Washington
Seattle, WA, USA

Colleen Delaney, MD, MSc
Director, Program in Cord Blood Transplantation
Associate Member, Clinical Research Division,
Fred Hutchinson Cancer Research Center
Associate Professor, Department of Pediatrics,
University of Washington School of Medicine,
Seattle, WA, USA

John F. DiPersio, MD, PhD
Professor of Medicine and Pathology and Immunology,
Deputy Director,
Siteman Cancer Center, Washington University School
of Medicine, St. Louis, MO, USA

Peter Dreger, MD
Professor of Medicine;
Head, Stem Cell Transplantation Unit,
Department of Internal Medicine V, University of
Heidelberg, Im Neuenheimer Feld 410,
Heidelberg, Germany

Katharine E. Duckworth, PhD
Assistant Professor,
Department of Medicine, Hematology, and Oncology,
Wake Forest Baptist Health, Comprehensive Cancer
Center of Wake Forest University,
Winston-Salem, NC, USA

Jarrod A. Dudakov, PhD
Senior Research Scientist,
Immunology Program, Memorial Sloan-Kettering
Cancer Center, New York, USA;
Department of Anatomy and Developmental Biology,
Monash University, Melbourne, Australia

Edgar G. Engleman, MD
Professor of Pathology and Medicine,
Stanford University School of Medicine;
Director, Stanford Blood Center,
Stanford, CA, USA

Sherif S. Farag, MD, PhD, MBBS
Lawrence H. Einhorn Professor of Oncology,
Department of Medicine, Indiana University School
of Medicine, Indianapolis, IN, USA

James L.M. Ferrara, MD, DSc
Professor of Cancer Medicine and Director,
Hematologic Malignancies Translational Research
Center, Tisch Cancer Institute,
Icahn School of Medicine at Mount Sinai,
New York, NY, USA

Jürgen Finke, MD
Professor,
Section of Allogeneic Stem Cell Transplantation,
Department of Internal Medicine I, Hematology,
Oncology and Stem Cell Transplantation,
Freiburg University Medical Center,
Freiburg im Breisgau, Germany

Mary E.D. Flowers, MD
Member,
Clinical Research Division, Fred Hutchinson Cancer
Research Center; Professor of Medicine, Department
of Medicine, University of Washington School of
Medicine, Seattle, WA, USA

Rosemary C. Ford, BA, BSN, OCN
Manager,
Transplant Clinic, Seattle Cancer Care Alliance,
Fred Hutchinson Cancer Research Center,
Seattle, WA, USA

Stephen J. Forman, MD
Chair,
Division of Hematology and Hematopoietic Cell
Transplantation, City of Hope Comprehensive Cancer
Center, Duarte, CA, USA

Noelle V. Frey, MD
Instructor of Medicine,
Division of Hematology–Oncology, Abramson Cancer
Center, University of Pennsylvania,
Philadelphia, PA, USA

Wilhelm Friedrich, MD
Professor of Pediatrics,
Department of Pediatrics, University Children's
Hospital Ulm, University of Ulm, Ulm, Germany

Jonathan R. Gavrin, MD
Clinical Professor,
Department of Anesthesiology and Critical Care,
Hospital of the University of Pennsylvania, Perelman
School of Medicine, Philadelphia, PA, USA

Javid Gaziev, MD, PhD, DMSc
Clinical Director,
International Center for Transplantation in Thalassemia
and Sickle Cell Anemia, Mediterranean Institute of
Hematology, Policlinico Tor Vergata, Rome, Italy

George E. Georges, MD
Associate Member,
Fred Hutchinson Cancer Research Center;
Associate Professor of Medicine, University of
Washington, Seattle, WA, USA

Morie A. Gertz, MD, MACP
Roland Seidler Jr. Professor of the Art of Medicine,
Mayo Medical School; Chair, Department of Medicine,
Mayo Distinguished Clinician, Mayo Clinic,
Rochester, MN, USA

Sergio A. Giralt, MD
Professor of Medicine,
Chief Attending Physician, Weill Cornell Medical
College; Chief Attending, Adult Bone Marrow
Transplant Service, Memorial Sloan-Kettering Cancer
Center, New York, NY, USA

Ted A. Gooley, PhD
Full Member,
Clinical Research Division,
Fred Hutchinson Cancer Research Center,
Duarte, CA, USA;
Affiliate Full Professor, Department of Biostatistics,
University of Washington, Seattle, WA, USA

Ajay K. Gopal, MD
Professor,
Medical Oncology Division,
University of Washington School of Medicine;
Fred Hutchinson Cancer Research Center,
University of Washington; Seattle Cancer Care Alliance,
Seattle, WA, USA

Masanori Hayashi, MD
Clinical Fellow in Pediatric Hematology–Oncology,
The Sidney Kimmel Comprehensive Cancer Center at
Johns Hopkins, Johns Hopkins University School of
Medicine, Baltimore, MD, USA

Helen E. Heslop, MD, FRACP, FRCPA
Dan L. Duncan Chair,
Professor of Medicine and Pediatrics, Center for Cell
and Gene Therapy, Baylor College of Medicine,
Houston Methodist Hospital and Texas Children's
Hospital, Houston, TX, USA

Diane Heye, BSN, OCN
Professional Practice Coordinator, Seattle Cancer Care
Alliance, Fred Hutchinson Cancer Research Center,
Seattle, WA, USA

Sangeeta Hingorani, MD, MPH
Assistant Professor,
Pediatrics, University of Washington,
Seattle Children's Hospital, Division of Nephrology,
Seattle, WA, USA

Hans H. Hirsch, MD
Professor,
Transplantation and Clinical Virology
and Division of Infection Diagnostics,
Department of Biomedicine, University of Basel;
Clinic for Infectious Diseases and Hospital
Epidemiology, University Hospital Basel,
Basel, Switzerland

Dora Y. Ho, MD, PhD
Clinical Associate Professor,
Department of Medicine,
Division of Infectious Diseases and
Geographic Medicine, Stanford University
School of Medicine School of Medicine,
Stanford, CA, USA

David M. Hockenbery, MD
Member,
Clinical Research Division,
Fred Hutchinson Cancer Research Center;
Professor of Medicine, University of Washington
School of Medicine, Seattle, WA, USA

Mary M. Horowitz, MD, MS
Chief, Division of Hematology and Oncology
Scientific Director, Center for International Blood
and Marrow Transplant Research
Medical College of Wisconsin,
Froedtert Clinical Cancer Center,
Milwaukee, WI, USA

Edwin M. Horwitz, MD, PhD
Director of Pediatric Blood and Marrow
Transplantation,
Professor of Pediatrics and Medicine,
Nationwide Children's Hospital,
The Ohio State University College of Medicine,
Columbus, OH, USA

James I. Ito, MD
Professor and Chief,
Division of Infectious Disease, City of Hope National
Medical Center, Duarte, CA, USA

Roy B. Jones, MD, PhD
Professor of Medicine,
Department of Stem Cell Transplantation and Cellular
Therapy, The University of Texas M.D. Anderson
Cancer Center, Houston, TX, USA

Carl H. June, MD
Richard W. Vague Professor in Immunotherapy,
Department of Pathology and Laboratory Medicine and
Smilow Center for Translational Research, Perelman
School of Medicine, University of Pennsylvania,
Philadelphia, PA, USA

Michael Kalos, PhD
CSO,
Cancer Immunobiology, Lilly Research Laboratories,
Eli Lilly and Company, New York, NY, USA

Jennifer A. Kanakry, MD
Head, Neoplasms of Immunodeficiency Unit,
Experimental Transplantation and Immunology
Branch, National Cancer Institute, National Institutes of
Health, Bethesda, MD, USA

Fouad R. Kandeel, MD, PhD
Professor,
Department of Diabetes and Metabolic Diseases
Research; Director, Division of Development and
Translational Diabetes and Endocrine Research;
Chair and Professor, Department of Clinical Diabetes,
Endocrinology, and Metabolism, City of Hope Medical
Center, Duarte, CA, USA

Hans-Peter Kiem, MD
Professor of Medicine,
University of Washington School of Medicine;
Member, Fred Hutchinson Cancer Research Center
Seattle, WA, USA

Amrita Krishnan, MD, FACP
Director,
Multiple Myelonia Program;
Associate Director, Medical Education and Training,
Department of Hematology/HCT, City of Hope
Medical Center, Duarte, CA, USA

Heather J. Landau, MD
Assistant Member and Assistant Attending Physician,
Adult Bone Marrow Transplant and Multiple
Myeloma Services,
Division of Hematologic Oncology, Department of
Medicine, Memorial Sloan Kettering Cancer Center;
Assistant Professor of Medicine,
Weill Cornell Medical College,
New York, NY, USA

Ginna G. Laport, MD
Professor of Medicine,
Stanford University Medical Center,
Division of Blood and Marrow Transplantation,
Stanford, CA, USA

Helen L. Leather, BPharm
Research Assistant;
Professor, Division of Hematology/Oncology,
University of Florida College of Medicine,
Gainesville, FL, USA

Stephanie J. Lee, MD, MPH
Member, Fred Hutchinson Cancer Research Center
Professor, University of Washington,
Seattle, WA, USA

Per Ljungman, MD, PhD
Professor of Hematology,
Department of Hematology, Karolinska University
Hospital; Section of Hematology, Department of
Medicine Huddinge, Karolinska Institute,
Stockholm, Sweden

Franco Locatelli, MD
Professor of Pediatrics,
University of Pavia, Pavia; Department of Pediatric
Hematology and Oncology, IRCCS, Ospedale
Pediatrico Bambino Gesù, Rome, Italy

David M. Loeb, MD, PhD
Associate Professor of Pediatrics and Oncology,
The Sidney Kimmel Comprehensive Cancer Center at
Johns Hopkins and Department of Pediatrics, Johns
Hopkins University School of Medicine, Baltimore,
MD, USA

Keith R. Loeb, MD, PhD
Associate Member,
Division of Clinical Research, Fred Hutchinson Cancer
Research Center; Associate Professor, Department
of Pathology, University of Washington School of
Medicine, Seattle, WA, USA

Aaron C. Logan, MD, PhD
Assistant Professor of Clinical Medicine,
Division of Hematology and Oncology,
University of California,
San Francisco, CA, USA

Robert Lowsky, MD
Professor of Medicine,
Division of Blood and Marrow Transplantation,
Department of Medicine,
Stanford University School of Medicine,
Stanford, CA, USA

Guido Lucarelli, MD
Director,
International Centre for Transplantation in
Thalassemia and Sickle Cell Anemia, Mediterranean
Institute of Hematology, Rome, Italy

Lowan K. Ly, PharmD
Clinical Pharmacist,
Hematopoietic Stem Cell Transplant,
University of Washington Medical Center,
Seattle, WA, USA

Margaret L. MacMillan, MD
Professor,
Blood and Marrow Transplant Program,
Children's Cancer Fund/Hageboeck Family
Chair in Pediatric Oncology,
McKnight Presidential Chair in Cancer Research,
Department of Pediatrics, University of Minnesota,
Minneapolis, MN, USA

Paula Charuhas Macris, MS, RD, CSO, FADA
Clinical Dietitian,
Seattle Cancer Care Alliance, Seattle, WA, USA

Kieren A. Marr, MD
Professor of Medicine and Oncology,
Johns Hopkins University,
and Sidney Kimmel Cancer Center,
Baltimore, MD, USA

Paul J. Martin, MD
Member,
Fred Hutchinson Cancer Research Center;
Professor of Medicine, University of Washington,
Seattle, WA, USA

Preface to the First Edition

The widespread application of bone marrow transplantation (BMT) to the treatment of a steadily increasing number of life-threatening hematological, oncological, hereditary, and immunological disorders is the culmination of more than four decades of research by many investigators. Early attempts in the 1950s to transplant living cells from one individual to another were carried out in the face of considerable skepticism. It was generally accepted as axiomatic that the immunological barrier to "foreign tissue" could never be overcome.

The horrors of Nagasaki and Hiroshima spurred interest in studies of the lethal effects of irradiation. It was discovered that mice given total body irradiation in doses lethal to the marrow could be protected from death by shielding the spleen or by an infusion of marrow, and that the marrow of such animals contained living cells of donor origin. These observations suggested that patients with leukemia might be given a lethal exposure of total body irradiation, which would destroy the malignant cells along with remaining normal marrow. The exposure would also destroy the immune system, making it possible to protect against lethality by a transplant of normal marrow cells.

The theory was correct, but results were disappointing. Because the procedure was both unproved and dangerous, only those patients who had no other options were considered. Except for a few patients with an identical twin donor, there were no survivors beyond a few months. Understanding of the human leukocyte antigen (HLA) system was not yet available, and little was known about the complication we now call graft-versus-host disease (GVHD). Thus, after a brief period of enthusiasm, most investigators abandoned this seemingly hopeless pursuit. Fortunately, work in animal models continued. Studies in inbred rodents defined the genetics of the major histocompatibility system and the fundamental rules of transplantation biology. Immunosuppressive drugs were developed to limit the severity of the immune reactions between donor and host. Demonstration of successful marrow transplants in the canine model using littermates matched for the major histocompatibility complex set the stage for successful transplantation of marrow between human siblings. Thus, it is clear that a long series of experimental studies in animals ultimately made human marrow transplantation possible.

By the late 1960s, much was known about the HLA system, more effective antibiotics were available, and platelet transfusions were becoming routine. Thus began the modern era of human BMT. The past 25 years have witnessed an almost exponential growth in the number of transplants being performed and the number of diseases being considered for BMT. Initially, most grafts employed marrow from an HLA-identical sibling. Autologous marrow, long known to be effective in animal systems, is now being used with increasing frequency following intensive cancer chemotherapy. Hematopoietic progenitor cells from the peripheral blood are now being used for BMT, either alone or to supplement marrow. As a result of increasing national and international cooperation, large panels of volunteer marrow donors of known HLA type are becoming available to patients whose own marrow cannot be used or who do not have a family donor.

Currently, thousands of transplants are being performed each year world-wide. With the demonstration that marrow could be transplanted and that the cure rate would be substantial, the logical step was taken to treat patients early during the course of their respective disease (i.e. in leukemia when the burden of malignant cells was relatively low and when the patient was in excellent clinical condition). With improved patient selection, development of improved tissue typing methods, availability of potent antimicrobial agents, advances in supportive care, and improved prevention of GVHD, the results of BMT have continued to improve.

Marrow transplantation is now being applied to a long list of diseases with a wide range of results depending on the disease, the type of transplant, and the stage of the disease. For some of the diseases, BMT has already proven to be the most effective therapy (e.g., some leukemias and severe aplastic anemia), whereas for others it is the only available curative treatment (e.g., thalassemia). In very rare genetic disorders, one successful BMT may establish the success of the treatment. For other more common disorders, controlled trials are necessary to define the proper role of allogeneic or autologous BMT, or therapy not involving BMT.

Only through rigorous study and long-term follow-up can novel approaches be confirmed as effective (or ineffective). For those working in the field of marrow transplantation, a source of intellectual satisfaction has been the interdisciplinary nature of the studies. A view of the wide-ranging disciplines involved can be gleaned by reading the chapter titles for this book. A successful BMT program is always a team effort. There must be cooperation between blood banks, referring physicians, radiation oncologists, immunologists, and physicians from many subspecialties. A dedicated support staff of technicians, data managers, and, above all, nurses, is crucial. The nursing team in particular is responsible for the day-to-day care of patients. Nurses not only provide the bedside management of complex protocol studies, but also bear the burden of emotional support through the difficult hospital period. They are the most readily available source of information for the patients and families day and night. Without a strong nursing team, the entire BMT program is jeopardized.

Most important are the patients who come to the transplant center with the courage to accept days, weeks, and sometimes months of discomfort in the hope of surviving a fatal disease. We must ensure that we acknowledge and respect the dignity and individuality of each patient, that we provide adequate information for informed decision making and then include patients and families in the decision process. The greatest reward for clinical investigators is to see patients reintegrated into their personal, social, and professional lives, free of their disease and its complications.

Summer, 1993

Preface to the Fifth Edition

Twenty-one years ago after the first edition and six years following the fourth edition of this textbook, the editors and publisher, Wiley-Blackwell, are proud to present the fifth edition of *Thomas' Hematopoietic Cell Transplantation*. The inspiration for the development of this fifth edition came from the rapid expansion of knowledge underlying transplantation biology, increased understanding of the complications of treatment, and new information related to the pathogenesis and treatment of diseases for which transplantation is utilized. The book also covers the expansion of stem-cell donor options and the genetic manipulation of cells of the hematopoietic and immune system.

In comparing this edition with the previous one, readers will find that there are new chapters focused on contributions to the field provided from basic science experiments in stem-cell biology, immunology, and tolerance. Along with these new chapters, previous contributions have been revised to reflect the deepening of our understanding of the benefits and challenges of transplantation and the impact of new therapies in the treatment of diseases for which transplant is a potentially curative therapy. In order to expand the information in each chapter, we have limited references to include only those that are most relevant.

New to the fifth edition is a companion digital edition replacing the CD ROM. The digital edition contains the entire text of the book in a searchable form and includes all the figures in a convenient downloadable format. The availability of the digital edition reflects changes in the way readers, including basic science and clinical investigators, clinicians, and nurses, access new information for both their research work and clinical care of patients.

We, the editors, also greatly appreciate the assistance of the staff at Wiley-Blackwell, who have been extremely helpful in the process of creating this new edition, now in two volumes, with a very different and modern cover presentation. The editors feel very proud to have assembled such a talented group of authors representing our colleagues who are experts in the clinical and basic science of transplantation. In addition, this edition would not have been possible without the dedicated work of our assistants, Sara E. Clark-Fuentes, Tanya Chiatovich, and, most importantly, Kimberlie Laramie. Finally, this edition honors the memory of Dr. Karl G. Blume and Dr. E. Donnall Thomas, who passed away in 2012. Their laboratory and clinical contributions helped begin and expand the field of transplantation as a curative therapy for patients suffering from leukemia and, over time, many other disorders. Both Dr. Thomas and Dr. Blume were the first two editors of the book and this edition is dedicated to them, and also to our patients and their families whose trusting partnership makes it possible to make progress and extend hope. We also honor the memory of Dr. Thomas' wife, Dottie, who we warmly consider to be the "mother" of hematopoietic cell transplantation, for her own contributions in helping Dr. Thomas and the field and for her support and editing of the first four editions of the book. They were our colleagues, mentors, and friends, and their impact will be felt in the field for many years to come.

Tribute

Our textbook honors Dr. E. Donnall Thomas, the single individual most responsible for creating the subject of this book, and Karl G. Blume, the Founder of the Transplant Programs both at City of Hope and Stanford University. Don and Karl were the first editors of this textbook and both passed away in the years following the publication of the fourth edition. We include this tribute as a remembrance of each of them, given the work that they did in their rich, professional lives to develop stem cell transplantation as a curative therapy for so many patients around the world.

E. DONNALL THOMAS, M.D.
March 15, 1920–October 20, 2012

Don was born on March 15, 1920, and was the son of a solo general practitioner in a small Texas village. As a child he often recalled accompanying his father to his small office and to patients' homes and between he and his father, they spanned the period from horse and buggy house calls to our modern high-tech medicine. Don received his B.A. and M.D. from the University of Texas where he met his wife, Dottie (September 18, 1922–January 9, 2015). Besides raising three children and eight grandchildren together, Dottie was Don's partner in every aspect of his professional life, from working in the laboratory to editing manuscripts and administering grants. Anyone who has been fortunate enough to work with Don knows that if he was the father of marrow transplantation, then Dottie was, without question, the mother, and we honor her memory as our friend and colleague in this tribute, too.

Don graduated from Harvard Medical School in 1947 and completed his internship and residency at Peter Bent Brigham Hospital in Boston. It was while in medical school that Don first became interested in normal and malignant hematopoiesis. During those years, Sidney Farber was initiating his first studies of the use of antifolates to treat children with acute leukemia, and Don witnessed the very first patient to achieve a remission with this approach. He was exposed to the pioneering work of Allan Erslev and his search for erythropoietin, and most importantly, he learned from Leon Jacobson and his studies showing that shielding the spleen protected mice from the otherwise lethal effects of total body irradiation. As data emerged that a similar irradiation protection effect could be achieved by transferring bone marrow from a nonirradiated to an irradiated mouse, Don became convinced of the clinical potential of marrow transplantation.

In 1955, Don moved to Cooperstown, New York, and the Mary Imogene Bassett Hospital, a Columbia University affiliate, where he began working on marrow transplantation both in the canine model and in humans with Dr. Joseph Ferrebee. In 1957, he published the first report on human patients, showing that complete remissions of leukemia could be achieved using total body irradiation followed by infusion of marrow from an identical twin. At that time, there was little understanding of the principles of human histocompatibility and so attempts to expand these studies to patients without identical twins were uniformly unsuccessful. These failures were the stimulus for a long series of experiments conducted by Don in the canine model, showing that it was possible to expose dogs to supralethal doses of irradiation and rescue them by reinfusing their own marrow, that the marrow could be cryopreserved, and that large doses of peripheral blood could substitute for marrow. However attempts at allogeneic transplantation in this outbred species continued to fail because of graft-versus-host disease or graft rejection.

In 1963, Don moved to Seattle and the University of Washington to become the first head of the Division of Oncology. There he developed techniques for rudimentary histocompatibility typing in the dog and, by the mid-1960s, showed that by selecting matched donors and using methotrexate posttransplant, it was possible to successfully transplant marrow between matched littermates in almost every case. At the same time, based on the work of Dausset, Payne, Amos, and others, understanding of human histocompatibility dramatically increased and so, in the late 1960s, Don made the decision to return to the subject of allogeneic transplantation in humans. He began to assemble a team of physicians, nurses, and support personnel (many of whom are still part of the current Seattle Transplant Program) and obtained a program project grant from the National Cancer Institute. In November 1968, Dr. Robert Good and his colleagues carried out the first marrow transplant from a matched sibling for an infant with immunodeficiency, and in March 1969, Don performed the first matched sibling donor transplant for a patient with leukemia.

The Seattle Transplant Program was originally housed at the Seattle Public Health Hospital, but in 1972, when the hospital was faced with closure by the federal government, the Program moved to Providence Hospital. In 1975, Don and his team moved to the newly created Fred Hutchinson Cancer Research Center, a move that provided Don with increased space, resources, and scientific collaborations. That same year, he and his colleagues published their classic *New England Journal of Medicine* paper summarizing the field of allogeneic transplantation and particularly the early Seattle experience. These results demonstrated not only the feasibility of the procedure but also that there was a plateau on the survival curves following transplantation, suggesting that some of these patients were cured with this novel technique. Don continued to lead the Clinical Research Division of the Center and its transplant program until his partial retirement in 1989. He continued writing manuscripts, delivering lectures, and participating in research discussions at the Center.

Appropriately, Don received almost every possible award for his work, including the American Society of Hematology's Henry M. Stratton Award, the General Motor's Kettering Prize, the American Society of Oncology's Karnofsky Award, the Presidential Medal of Science, and, of course, the 1990 Nobel Prize in Medicine which he shared with Joseph Murray. With each award, Don always emphasized how much of his work was a team effort. He invariably mentioned the contributions of Rainer Storb, Dean Buckner, Reg Clift, Paul Neiman, Alex Fefer, and Bob Epstein, who helped form the original Seattle Transplant Team, and of Ted Graham, who moved with Don from Cooperstown to help in the animal research. Don never failed to credit the nursing and support staff who played such a critical role in these efforts and, like Karl, always acknowledged the patients and their families who were true partners in his work.

KARL G. BLUME, M.D.
April 10, 1937–January 9, 2013

Karl G. Blume was born in Germany on April 10, 1937; he received his medical education under the mentorship of Professor Georg W. Löhr at the University of Freiburg and graduated in 1963. After graduation he undertook his residency at Marburg and then held two fellowships: one at Freiburg and the other at City of Hope in 1970 and 1971, respectively. His early work was in red cell biochemistry, and he pursued his postdoctoral fellowship under Dr. Ernest Beutler.

In 1975, after discussions with Dr. E. Donnall Thomas in Seattle and with his encouragement, Dr. Beutler decided to develop an allogeneic bone marrow transplantation (BMT) program at City of Hope and recruited Karl to return to City of Hope to establish the program. The program at City of Hope was, in many ways, derived from work and discussions that Karl had with colleagues at the Fred Hutchinson Cancer Research Center and resulted in lifelong friends from those early days of the development of transplantation to treat diseases of bone marrow and immune system origin. The first transplantation at City of Hope was performed on May 18, 1976.

Karl's clinical and research work focused on the problems that confront patients undergoing transplantation, namely, prevention of relapse, understanding the process of immune reconstitution, the treatment and prevention of graft-versus-host disease and cytomegalovirus infection management, and, among his early insights, issues related to patients' quality of life after transplantation and their long-term health. In 1981, Karl was the principal investigator for City of Hope's National Cancer Institute's first approved program project grant in transplantation, which contained projects that focused on those problems, and he organized a talented group of young laboratory and clinical scientists to work together in understanding and solving these challenges. He published the first results from City of Hope on the transplants for acute leukemia in the *New England Journal of Medicine* in 1981, showing the impact of remission status on outcome.

Based on his success at City of Hope, in 1987 Karl was recruited by Stanley Schrier and Ron Levy to begin a new transplant program at Stanford University. Thus, he again developed from scratch his second successful transplantation program, mentoring numerous young physicians and inspiring colleagues and staff to work with him in a common quest to cure patients with hematologic malignancy and return them to their normal lives. Just as he had done at City of Hope, he developed and led another successful program project grant application. He also established the Division of Blood and Marrow Transplantation at Stanford University, taking a personal interest in the lives of each of his patients, incorporating all aspects of the care team into their treatment, including nursing, social work, dietary, and physical therapy, and confirming again a model for patient care and research in use at transplant programs around the country. During that time, he trained both Rob Negrin and Nelson Chao, who went on to direct transplantation programs at Stanford University and at Duke University, respectively. Therefore, Karl was responsible for at least three of the major BMT programs in the United States, not to mention the numerous fellows he trained and mentored at City of Hope and Stanford University.

In 2000, Karl attained emeritus status at Stanford University and stepped down from the role of chief of the BMT division to develop the Stanford Cancer Institute. He continued to serve Stanford University as associate director of research in the Department of Medicine. In 2003, he directed his energies toward developing and achieving the coveted National Cancer Institute-designated cancer center status for the Stanford Cancer Institute, a first for the university.

Karl was also a driving force in 1994 in the founding of the American Society of Blood and Marrow Transplantation, now an international organization for physicians and researchers committed to serving patients with a variety of blood diseases. He was also a leader in the American Society of Hematology and, for many years, was in charge of the organization's Career Development Program. Early on, he recognized that our responsibilities were not only to our patients now but also to those who come to us in the future. He became the first honorary member of ASBMT and, with Richard O'Reilly, was the first coeditor of *The Biology of Blood and Marrow Transplantation*, the major journal in the field. Karl worked tirelessly to make it the central journal in the field, and when there were questions about the cost of the first issues, he made a personal financial donation to ensure the journal's successful launch.

Karl won many honors, both in the United States and Germany, but his major legacy is the impact he had on the thousands of patients he treated and the others he inspired to follow in his footsteps. All of us who knew and loved him knew that his highest priorities remained the quality of life of his patients and their families and the well-being of his transplantation team and those of his colleagues around the country and world. He held us all to high standards of excellence, but he maintained it with wonderful warmth, humor, and sensitivity over the decades and across continents. All of us who worked with him benefited from his respect and could always count on him to extend a helping hand and open ears, as he wanted nothing more than to help, to give of himself, and to be a force for good in this world.

In addition to his interest in music, sports – especially Stanford athletics – and the politics of the world and its impact on all of us, he was an exemplary family man. His children, Philipp and Caroline, could always rely on him for advice, affection, and guidance. In his last years, the lives and activities of his grandchildren, Adrian, Katie, Laura, Kevin, and David, were his focus and, of course, they adored him. Vera, his wife of 45 years, was his partner in his life and his work, as Dottie was to Don, and, at difficult times, always his source of strength and calm.

Although Don and Karl are most noted for their leadership and pioneering scientific achievements, for those of us who have been fortunate enough to work with them, they are equally admired for the way in which they achieved their success. They were always focused, hardworking, and uncompromising in their laboratories and especially in clinical research. They could both be demanding critics and held others accountable for their actions, yet at the same time, they were always generous with their ideas, loyal to their colleagues, and quick to deflect praise to their coworkers and help younger colleagues who chose this career.

For many of us in the field who had the privilege of knowing and working with both Don and Karl and for the many patients who are alive because of their work and dedication, the sentiment of a Hebrew proverb seems appropriate for each of them: "Say not in grief he is no more, but live in thankfulness that he was."

List of Abbreviations

AA	Amyloid A
AA	Aplastic anemia
AABB	American Association of Blood Banks
aaIPI	Age-adjusted International Prognostic Index
AAV	Adeno-associated virus
ABC	Activated B-cell-like
ABL	Abelson leukemia virus
aBMT	Autologous bone marrow transplantation
ABMTR	Autologous Blood and Marrow Transplant Registry – North America
ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine
ABW	Actual body weight
AC	Adriamycin (doxorubicin), cyclophosphamide
ACE	Adriamycin (doxorubicin), cyclophosphamide, etoposide
ACEI	Angiotensin-converting enzyme inhibitor
ACIF	Anticomplement immunofluorescence
ACIP	Advisory Committee on Immunization Practices
ACOR	Association of Online Cancer Resources
ACP	Advanced care planning
ACR	Albumin-to-urine creatinine ratio
ACS	Acute chest syndrome
ACTH	Adrenocorticotropic hormone
ACVBP	Adriamycin (doxorubicin), cyclophosphamide, vindesine, bleomycin, prednisone
AD	Autoimmune disease
ADA	Adenosine deaminase
ADCC	Antibody-dependent cell-mediated cytotoxicity
ADH	Antidiuretic hormone
ADL	Activities of daily living
AdV	Adenovirus
AEL	Acute erythroleukemia
AFP	α-Fetoprotein
AGM	Aorta–gonad–mesonephros (region)
aGVHD	Acute graft-versus-host disease
AH	Ancestral haplotype
aHCT	Autologous hematopoietic cell transplantation
AHNMD	Associated clonal hematologic non-mast-cell lineage disease
AHPCS	Autologous hematopoietic progenitor-cell support
aHR	Adjusted hazard ratio
AHRQ	Agency for Health Care Research and Quality
aHUS	Atypical hemolytic uremic syndrome
AIDS	Acquired immune deficiency syndrome
AIF	Apoptosis-inducing factor
AIHA	Autoimmune hemolytic anemia
AIRE	Autoimmune regulator
AITD	Autoimmune thyroid disease
AITL	Angioimmunoblastic T-cell lymphoma
AKI	Acute kidney injury
AKIN	Acute Kidney Injury Network
aKIR	Activating killer immunoglobulin-like receptor
AL	Amyloid light-chain
ALA	α-Lipoic acid
ALC	Absolute lymphocyte count
ALCL	Anaplastic large-cell lymphoma
ALDH	Aldehyde dehydrogenase
ALG	Antilymphocyte globulin
ALK	Anaplastic lymphoma kinase
ALL	Acute lymphoblastic leukemia
AlloHCT	Allogeneic hematopoietic cell transplantation
AlloSCT	Allogeneic stem-cell transplantation
ALP	Alkaline phosphatase
ALPS	Autoimmune lymphoproliferative syndrome
ALT	Alanine aminotransferase
AMA	Antimitochondrial antibody
AMKL	Acute megakaryoblastic leukemia
AML	Acute myeloid leukemia
ANC	Absolute neutrophil count
ANKL	Aggressive natural killer cell leukemia
AOTONJ	Antiosteoclastic therapy-associated osteonecrosis of the jaws
AP	Accelerated phase
AP-1	Activator protein-1
APACHE	Acute Physiology, Age, Chronic Health Evaluation
APBMT	Asia Pacific Blood and Marrow Transplantation
APC	Antigen-presenting cell
APECED	Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy
API	4′,6-Diamidino-2-phenylindole
APL	Acute promyelocytic leukemia
APMF	Acute panmyelosis with myelofibrosis
Ara-C	Cytosine arabinoside
ARB	Angiotensin receptor blocker
ARDS	Acute or adult respiratory distress syndrome
ARF	Acute renal failure
ARL	AIDS-related lymphoma
ARS	Acute radiation syndrome
ARSA	Arylsulfatase A
ART	Assisted reproductive technology
ASBMT	American Society for Blood and Marrow Transplantation
ASCT	Autologous stem-cell transplantation
ASO	Allele-specific oligonucleotide
ASO-PCR	Allele-specific oligonucleotide polymerase chain reaction
AST	Aspartate aminotransferase
AT	Alkyltransferase
ATG	Antithymocyte globulin
ATL	Adult T-cell leukemia
ATLL	Adult T-cell leukemia/lymphoma
ATM	Ataxia Telangiectasia Mutated
ATRA	All-*trans*-retinoic acid
AUC	Area under the curve
AutoHCT	Autologous hematopoietic cell transplantation
AVP	Arginine vasopressin
AYA	Adolescent and young adult
AZT	Zidovudine
BAEP	Brainstem auditory evoked potentials
BAFF	B-cell-activating factor
BAIAP3	Brain-specific angiogenesis inhibitor 1-associated protein 3
BAL	Bronchoalveolar lavage
BC	Blast crisis

BCC	Basal cell carcinoma
BCMA	B-cell maturation antigen
BCNA	Bicyclic nucleoside analog
BCNU	1,3-Bis(2-chloroethyl)-1-nitrosourea (carmustine)
BCR	B-cell receptor
BCR	Breakpoint cluster region
BD	Bortezomib, dexamethasone
BDP	Beclomethasone 17,21-dipropionate
BEAC	BCNU, etoposide, Ara-C (cytosine arabinoside), cyclophosphamide
BEAM	BCNU, etoposide, Ara-C (cytosine arabinoside), melphalan
BED	Biologically effective dose
BEP	Bleomycin, etoposide, cisplatin
BER	Base excision repair
BFI	Brief Fatigue Inventory
BFM	Berlin–Frankfurt–Münster
BFU-E	Burst-forming units – erythroid
BIW	Twice weekly
BL	Burkitt lymphoma
BLA	Biologics license application
BL-CFC	Blast colony-forming cell
BLS	Bare lymphocyte syndrome
BLyS	B-lymphocyte stimulator
BM	Bone marrow
BMC	Bone marrow cell
BMD	Bone mineral density
BMDW	Bone Marrow Donors Worldwide
BMFS	Bone marrow failure syndromes
BMI	Body mass index
BMSC	Bone marrow stem cell
BMSCT	Blood and Marrow Stem Cell Transplant
BMT CTN	Blood and Marrow Transplant Clinical Trials Network
BMT	Bone marrow transplantation
BMTCN	Blood and Marrow Transplantation Certified Nurse
BMTinfonet	Blood and Marrow Transplant Information Network
BMTSS	Bone Marrow Transplant Survivor Study
BNLI	British National Lymphoma Investigation
BNP	Brain natriuretic peptide
BO	Bronchiolitis obliterans
BOOP	Bronchiolitis obliterans organizing pneumonia
BPDCN	Blastic plasmacytoid dendritic cell neoplasm
BPI	Bactericidal/permeability-increasing
BPI	Brief Pain Inventory
BR	Bendamustine, rituximab
Breg	Regulatory B (cell)
BSE	Bovine spongiform encephalopathy
BSI	Brief symptom inventory
BTK	Bruton's tyrosine kinase
BTLA	B- and T-lymphocyte attenuator
BU	Busulfan
BuMel	Busulfan, melphalan
BUN	Blood urea nitrogen
C1P	Ceramide-1 phosphate
CABSI	Catheter-associated bloodstream infection
CAEBV	Chronic active Epstein–Barr virus
CALGB	Cancer and Acute Leukemia Group B
CALLA	Common acute lymphoblastic leukemia antigen
CAR	Chimeric antigen receptor
CAR	Cocksackie and adenovirus receptor
CAR	CXCL12 adventitial reticular cell
CARES	Cancer Rehabilitation Evaluation System
cART	Combination antiretroviral therapy
CB	Cord blood
CBC	Cord blood cell
CBF	Core binding factor
CBG	Corticosteroid-binding globulin
CBHC	Cord blood hemapoietic cell
CBSC	Cord blood stem cell
CBT	Cognitive–behavioral therapy
CBT	Cord blood transplantation
CBV	Cyclophosphamide, BCNU, etoposide
CC	Complete chimerism
CCG	Children's Cancer Group
CCI	Charlson Comorbidity Index
CCI	Corrected count increment
CCNU	1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea
CCR	Cytologic complete remission
CCSG	Children's Cancer Study Group
CCyR	Complete cytogenetic remission
CDA	Cytidine deaminase
CDAD	*Clostridium difficile*-associated diarrhea
CDAI	Crohn Disease Activity Index
CDC	Centers for Disease Control and Prevention
CDC	Complement-dependent cytotoxicity
CDF	Cumulative distribution function
CDK	Cyclin/cyclin-dependent kinase
CE	Carboplatin, etoposide
CEA	Carcinoembryonic antigen
CEACAM	Carcinoembryonic-antigen-related cell-adhesion molecule
CEC	Carboplatin, etoposide, cyclophosphamide
CEL-NOS	Chronic eosinophilic leukemia-not otherwise specified
CEM	Carboplatin, etoposide, melphalan
CESD	Center for Epidemiologic Studies – Depression
CFAR	Cyclophosphamide, fludarabine, alemtuzumab, rituximab
CFH	Complement factor H
CFU	Colony-forming unit
CFU-B	Colony-forming unit – B-lymphocyte
CFU-BLAST	Colony-forming unit – blast
CFU-E	Colony-forming unit – erythroid
CFU-F	Colony-forming unit – fibrolast
CFU-GEMM	Colony-forming unit – granulocyte/erythroid/macrophage/megakaryocyte
CFU-GM	Colony-forming unit – granulocyte–macrophage
CFU-MEG	Colony-forming unit – megakaryocytic
CFU-Mix	Colony-forming unit – mixed
CFU-S	Colony-forming unit – spleen
CFU-T	Colony-forming unit – T-lymphocyte
CGD	Chronic granulomatous disease
CGH	Comparative genomic hybridization
cGVHD	Chronic graft-versus-host disease
CHD	Coronary heart disease
CHF	Congestive heart failure
CHOEP-14	Doxorubicin, vincristine, etoposide, prednisone
CHOP	Cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone
CHR	Complete hematologic response
CHRIs	Child Health Ratings Inventory
CHS	Chediak–Higashi syndrome
CI	Comorbidity index
CI	Confidence interval
CI	Cumulative incidence
CIA	Collagen-induced arthritis
CIBMTR	Center for International Blood and Marrow Transplant Research
CID	Combined immunodeficiency syndrome
CIDP	Chronic inflammatory demyelinating polyneuropathy
CIF	Cumulative incidence function
CIHHV-6	Chromosomal integration of human herpesvirus 6
CIPN	Critical illness polyneuropathy
CJD	Creutzfeldt–Jakob disease
CKD	Chronic kidney disease
CLIA	Clinical Laboratory Approved Amendments
CLL	Chronic lymphoid/lymphocytic leukemia
CLO	Clofarabine

CLP	Common lymphoid progenitor
CLR	C-type lectin receptor
CMF	Cyclophosphamide, methotrexate, fluorouracil
CMI	Cellular mediated immunity
CML	Chronic myeloid/myelogenous leukemia
CMML	Chronic myelomonocytic leukemia
CMN	Chronic myeloid neoplasm
CMP	Common myeloid progenitor
CMR	Complete molecular response
CMV	Cytomegalovirus
CMV-Ig	Cytomegalovirus antibody-enriched intravenous immunoglobulin
CMV-IP	Cytomegalovirus-associated interstitial pneumonia
CNI	Calcineurin inhibitor
CNL	Chronic neutrophilic leukemia
CNS	Central nervous system
COG	Children's Oncology Group
ConA	Concanavalin A
COP	Cryptogenic organizing pneumonia
COPE	Coping Orientations to Problems Experienced Scale
COX-2	Cyclooxygenase-2 (inhibitor)
CP	Chronic phase
CR	Complete remission
CRBSI	Catheter-related bloodstream infection
CREG	Cross-reactive group
CRM	Continual reassessment method
CRS	Cytokine release syndrome
CRVT	Catheter-related venous thrombosis
CSA	Cyclosporine A
CSF	Cerebrospinal fluid
CSF	Colony-stimulating factor
CSP	Cyclosporine
CT	Computed tomography
CT	Cyclophosphamide, thioTEPA
CTC	Cyclophosphamide, thioTEPA, carboplatin
CTC	Cytotoxic T cell
CTCL	Cutaneous T-cell lymphoma
CTD	Cyclophosphamide, thalidomide, dexamethsone
CTL	Cytotoxic T-lymphocyte
CTLA	Cytotoxic T-lymphocyte antigen
CTLP	Cytotoxic T-lymphocyte precursor
CTN	Clinical Trials Network
CTX	Cyclophosphamide
CTXD	Cancer and Treatment Distress
CTZ	Chemotactic trigger zone
CVAD	Fractionated cyclophosphamide, vincristine, adriamycin, dexamethasone
CVC	Central venous catheter
CVD	Cardiovascular disease
CVID	Common variable immune deficiency
CVRF	Cardiovascular risk factor
CVVH	Continuous veno-venous hemofiltration
CVVHDF	Continuous veno-venous hemodiafiltration
CY	Cyclophosphamide
CyBorD	Cyclophosphamide, bortezomib, dexamethasone
CYP	Cytochrome P
DAD	Direct antigen detection
DAF	Decay-accelerating factor
DAG	Diacylglycerol
DAH	Diffuse alveolar hemorrhage
DAMP	Damage-associated molecular pattern
DAS	Dasatinib
DC	Dendritic cell
DCEP	Dexamethasone, cyclophosphamide, etoposide, cisplatin
DCK	Deoxycytidine kinase
DDR	Discoidin domain receptor
DFA	Direct fluorescent antibody (test)
DFCI	Dana–Farber Cancer Institute
DFS	Disease-free survival
DGK	Deoxyguanosine kinase
DH	Double hit
DHAP	Dexamethasone, high-dose cytarabine, cisplatin
DHEA	Dehydroepiandrosterone
DHEAS	Dehydroepiandrosterone sulfate
DHFR	Dihydrofolate reductase
DHPG	9-(1,3-Dihydroxy-2-propoxymethyl)guanine (ganciclovir)
DIC	Disseminated intravascular coagulation
DILI	Drug-induced liver injury
DIPSS	Dynamic International Prognostic Scoring System
DKA	Diabetic ketoacidosis
DLA	Dog leukocyte antigen
DLBCL	Diffuse large B-cell lymphoma
DLCL	Diffuse large cell lymphoma
DLCO	Diffusion capacity of the lung for carbon monoxide
DLI	Donor lymphocyte infusion
DLT	Dose-limiting toxicity
DM	Diabetes mellitus
DMSO	Dimethyl sulfoxide
DN	Double negative
DNA	Deoxyribonucleic acid
DNAX	DNA accessory molecule
DNR	Do not resuscitate
DOTA	1,4,7,10-Tetraazacyclododecane-*N*,*N*′,*N*′′,*N*′′′-tetraacetic acid
DOTMP	1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetramethylenephosphonic acid
DPC	Days post-coitum
DPTS	Delayed pulmonary toxicity syndrome
DR	Death receptor
DRG	Dorsal root ganglion
DSA	Donor-specific antibody
DSB	Double-strand break
DSII	Disease-Specific Impairment Inventory
DSRCT	Desmoplastic small round cell tumor
dsRNA	Double-stranded RNA
DST	Donor-specific transfusion
DTH	Delayed type hypersensitivity
DTI	Diffusion-tensor MRI
DTPA	Diethylenetriaminepentaacetic acid
DVT	Deep venous thrombosis
DXA	Dual-energy X-ray absorptiometry
EAE	Experimental allergic encephalomyelitis
EAE	Experimental autoimmune encephalomyelitis
EATL	Enteropathy-associated T-cell lymphoma
EB	Embryoid body
EBMT	European Group for Blood and Marrow Transplantation
EBMTR	European Bone Marrow Transplant Registry
EBNA	Epstein–Barr (virus) nuclear antigen
EBV	Epstein–Barr virus
EBV-LDP	Epstein–Barr virus-associated lymphoproliferative disorder
EC	Endothelial cell
EC	Epirubicin, cyclophosphamide
ECAT	Extracorporal adsorption therapy
ECFC	Endothelial colony-forming cells
ECG	Electrocardiogram
ECIL	European Conference on Infections in Leukaemia
ECM	Extracellular matrix
ECP	Extracorporeal photopheresis
ED	Erectile dysfunction
EDSS	Expanded Disability Status Scale
EDTMP	Ethylenediaminetetramethylenephosphonic acid
EEG	Electroencephalogram
EFS	Event-free survival
EGBMT	European Group for Blood and Marrow Transplantation
ELISA	Enzyme-linked immunosorbent assay

ELN	European LeukemiaNet
EM	Erythema multiforme
EMLA	Eutectic Mixture of Local Anesthetic
EN	Enteral nutrition
ENKL	Extranodal NK/T-cell nasal type leukemia
ENSG	European Neuroblastoma Study Group
ENU	Ethyl-*N*-nitrosourea
EORTC	European Organization for Research and Treatment of Cancer
EPC	Endothelial progenitor cell
EPO	Erythropoietin
EPOCH	Etoposide, prednisone, vincristine (Oncovin), doxorubicin hydrochloride
ER	Endoplasmic reticulum
ER	Estrogen receptor
ERIC	European Research Initiative in chronic lymphocytic leukemia
ERT	Enzyme replacement therapy
ESBL	Extended-spectrum β-lactamase
ESC	Embryonic stem cell
ESFT	Ewing sarcoma family of tumors
ET	Essential thrombocythemia
ETP	Early thymic progenitor
ETS	Euthyroid sick syndrome
EWOG	European Working Group
EWOG-MDS	European Working Group of Myelodysplastic Syndromes in Childhood
FA	Fanconi anemia
FAB	French–American–British Classification
FACIT-SP	Functional Assessment of Chronic Illness Therapy – Spirituality and Wellbeing Scale
FACS	Fluorescence-activated cell sorter
FACT	Foundation for the Accreditation of Cellular Therapy
FACT	Functional Assessment of Chronic Illness Therapies
FACT-BMT	Functional Assessment of Cancer Therapy – BMT Module
FAMA	Fluorescent-antibody staining of membrane antigen
FasL	Fas ligand
FC	Facilitator cell
FCH	Fibrosing cholestatic hepatitis
FCR	Fludarabine, cyclophosphamide, rituximab (RTX)
FDA	Food and Drug Administration
FDG	[^{18}F]Fluorodeoxyglucose
FDR	False discovery rate
FEC	Fluorouracil, epirubicin, cyclophosphamide
$\mathbf{FEV_1}$	Forced expiratory ventilation in 1 second
FFP	Fresh frozen plasma
FFS	Failure-free survival
FHCRC	Fred Hutchinson Cancer Research Center
FISH	Fluorescence in situ hybridization
FKBP	Tacrolimus (FK)-binding protein
FL	Follicular lymphoma
FLACC	Face, Legs, Activity, Cry, Consolability (pain assessment tool)
FLAIR	Fluid attenuated inversion recovery
FLC	Free light chain
FLIPI	Follicular Lymphoma International Prognostic Index
FLU	Fludarabine
FN	Febrile neutropenia
FNA	Fine-needle aspiration
FNH	Focal nodular hyperplasia
FoxP3	Forkhead box P3
FSH	Follicle-stimulating hormone
FSI	Fatigue Symptom Inventory
FTBI	Fractionated total body irradiation
FTBI	Full total body irradiation
FTI	Farnesyltransferase inhibitor
FTOC	Fetal thymic organ culture
5-FU	5-Fluorouracil
FVC	Forced vital capacity
GA	Glatiramer acetate
GABG	German Autologous Bone Marrow Transplant Group
GALT	Gut-associated lymphoid tissue
GAP	GTPase-activating protein
GBM	Glioblastoma multiforme
G-BM	G-PBHC and/or G-CSF primed bone marrow
gc	Genome copies
GCB	Germinal center B-cell-like
G-CSF	Granulocyte colony-stimulating factor
GCT	Germ-cell tumor
GDP	Guanosine diphosphate
GEBDIS	German Breast Cancer Dose Intensity Study
GEE	Generalized estimating equation
GEL/TAMO	Grupo Español de Linfomas/Trasplante Autólogo de Médula Ósea
GEM	Gemcitabine
GEM	Grid Enabled Measures
GEP	Gene expression profiling
GF	Graft failure
GFP	Green fluorescent protein
GFR	Glomerular filtration rate
GGT	γ-Glutamyl transferase
GH	Growth hormone
GHRH	Growth hormone-releasing hormone
GHSG	German Hodgkin Study Group
GI	Gastrointestinal (tract)
GICAT	Gruppo Italiano Collaborativo AIDS e Tumori (Italian Cooperative Group on AIDS and Tumors)
GISL	Gruppo Italiano per lo Studio dei Linfomi (Italian Lymphoma Study Group)
GITMO	Gruppo Italiano per il Trapianto di Midollo Osseo
GM	Galactomannan
GM-CSF	Granulocyte–macrophage colony-stimulating factor
GMP	Granulocyte macrophage progenitor (cell)
GMP	Guanosine monophosphate
GNB	Gram-negative bacilli
GnRH	Gonadotropin-releasing hormone
gp	Glycoprotein
G-PBHC	Granulocyte colony-stimulating factor-mobilized peripheral blood hematopoietic cell
GPI	Glycosylphosphatidylinositol
GPI-AP	Glycosylphosphatidylinositol-anchored protein
GRE	Glucocorticoid response element
GSH	Glutathione (reduced)
GST	Glutathione-*S*-transferase
GTP	Good tissue practice
GTP	Guanosine triphosphate
GVD	Gemcitabine, vinorelbine, liposomal doxorubicin
GVH	Graft-versus-host
GVHD	Graft-versus-host disease
GVHL	Graft-versus-Hodgkin disease (lymphoma)
GVL	Graft-versus-leukemia
GVLE	Graft-versus-leukemia effect
GVT	Graft-versus-tumor
GWAS	Genome-wide association study
H&E	Hematoxylin and eosin (stain)
HA	Hemagglutinins
HAART	Highly active antiretroviral therapy
HADS	Hospital Anxiety and Depression Scale
HAMA	Human antimouse antibody
HA-MRSA	Healthcare-associated MRSA
HAV	Hepatitis A virus
HBoV	Human bocavirus
HBV	Hepatitis B virus
HC	Hematopoietic cell
HC	Hemorrhagic cystitis
HC	Histocompatibility complex

4-HC	4-Hydroperoxycyclophosphamide
HCG	Human chorion gonadotropin
HCoV	Human coronavirus
HCT	Hematopoietic cell transplantation
HCT-CI	HCT-Comorbidity Index
HCV	Hepatitis C virus
HD	Hodgkin disease
HDAC	High-dose Ara-C
HDC	High-dose chemotherapy
HDIT	High-dose immunosuppressive therapy
HDT	High-dose therapy
HEPA	High-efficiency particulate air
HES	Hydroxyethyl starch
HES	Hypereosinophilic syndrome
hESC	Human embryonic stem cell
HEV	Hepatitis E virus
HFTBI	Hyperfractionated total body irradiation
HGF	Hepatocyte growth factor
HGNC	HUGO Genome Nomenclature Committee
HHS	Human and Health Services
HHV	Human herpesvirus
HI	Hemagglutination inhibition
HIB	*Haemophilus influenzae* type B
HIF	Hypoxia-inducible transcription factor
HIV	Human immunodeficiency virus
HL	Hodgkin lymphoma
HLA	Human leukocyte antigen
HLH	Hemophagocytic lymphohistiocytosis
hMPV	Human metapneumovirus
HOVON	Hemato-Oncologie voor Volwassenen Nederland
HPA	Hypothalamic–piuitary–adrenal
HPC	Hematopoietic progenitor cell
HPI	Helicase–primase inhibitor
HPV	Human papillomavirus
HR	Hazard ratio
HR	Homologous recombination
HRCT	High-resolution chest tomography
HRE	Hypoxia-inducible transcription factor response element
HRhV	Human rhinovirus
HRPBC	High-risk primary breast cancer
HRQOL	Health-related quality of life
HRSA	Health Resources and Services Administration
HRT	Hormone replacement therapy
HSC	Hematopoietic stem cell
HSC	Hepatic stellate cell
HSCT	Hematopoietic stem-cell transplantation
HSDD	Hypoactive sexual desire disorder
HSPC	Hematopoietic stem/progenitor cell
HSTCL	Hepatosplenic T-cell lymphoma
HSV	Herpes simplex virus
HSV-TK	Herpes simplex virus thymidine kinase
HT	Histologic transformation
5-HT	5-Hydroxytryptamine (serotonin)
hTERT	Human telomerase reverse transcriptase
HTLV	Human T-cell lymphotropic virus
HTS	High-throughput sequencing
HU	Hydroxyurea
HUS	Hemolytic uremic syndrome
HVEM	Herpes virus entry mediator
HVG	Host-versus-graft (reaction)
IA	Invasive aspergillosis (infection)
IBCSG	International Breast Cancer Study Group
IBDIS	International Breast Cancer Dose Intensity Study
IBMTR	International Bone Marrow Transplant Registry
IBW	Ideal body weight
ICAM	Intracellular adhesion molecule
ICE	Ifosfamide, carboplatin, etoposide

ICOS	Inducible costimulator (protein)
ICOS-L	Inducible costimulator ligand
ICSI	Intracytoplasmic sperm injection
ICU	Intensive care unit
ID	Intermediate dose
iDC	Immature dendritic cells
IDO	Indoleamine 2,3-dioxygenase
IDOX	4-Iodo-4-deoxydoxorubicin
IDSA	Infectious Diseases Society of America
IE	Immediate early (antigen expression)
IEM	Inborn errors of metabolism
IFI	Invasive fungal infection
IFN	Interferon
IFRT	Involved field radiotherapy
Ig	Immunoglobulin
IGCCCG	International Germ Cell Cancer Collaborative Group
IGEV	Ifosfamide, gemcitabine, vinorelbine, prednisone
IGF	Insulin-like growth factor
IGFBP	Insulin-like growth factor binding protein
IgG	Immunoglobulin G
IgH	Immunoglobulin heavy chain
IGRT	Image-guided radiation therapy
IHC	Immunohistochemistry
IHWG in HCT	International Histocompatibility Working Group in Hematopoietic Cell Transplantation
iKIR	Inhibitory killer immunoglobulin-like receptor
IL	Interleukin
IM	Imatinib
IMGT	International ImMunoGenetics
IMID	Immunomodulatory drug
IMPDH	Inosine monophosphate dehydrogenase
IMRT	Intensity-modulated radiation therapy
IMWG	International Myeloma Working Group
IND	Improvised nuclear device
IND	Investigational new drug
iNK-T	Invariant natural killer T (cell)
iNOS	Inducible NO synthase
INR	International normalized ratio
INRG	International Neuroblastoma Risk Group
INRGSS	International Neuroblastoma Risk Group Staging System
INSS	International Neuroblastoma Staging System
INSTI	Integrase strand transfer inhibitor
IORT	Intraoperative radiotherapy
IP	Interstitial pneumonia
IP_3	Inositol-1,4,5-triphosphate
IPD	Invasive pneumococcal disease
IPEX	Immunodysregulation polyendocrinopathy enteropathy X-linked (syndrome)
IPFSG	International Prognostic Factor Study Group
IPI	International Prognostic Index
iPS	Induced pluripotent stem
IPS	Idiopathic pneumonia syndrome
IPS	Interstitial pneumonia syndrome
IPSS	International Prognostic Scoring System
IPV	Inactivated polio vaccine
IRB	Institutional Review Board
IRF	Interferon regulatory factor
IRSG	Intergroup Rhabdomyosarcoma Study Group
IS	Immune synapse
IS	Immunosuppressive
IS	International Scale
ISC	Intestinal stem cell
ISO	Isohemagglutinin
IST	Immunosuppressive therapy
ISW	Immune suppression withdrawal
ITAM	Immunoreceptor tyrosine-binding activation motif
ITCC	Innovative Therapies for Children with Cancer

ITD	Internal tandem duplication
ITIM	Immunoreceptor tyrosine-binding inhibition motif
iTreg	Induced regulatory T (cell)
ITT	Intent-to-treat
IUPM	Infectious units per million
IV	Intravenous
IVF	In vitro fertilization
IVF	Intravenous fluid
IVIg	Intravenous immunoglobulin
IκB	Inhibitor I kappa B
JACIE	Joint Accreditation Committee of ISCT-Europe and EBMT
JAK	Janus kinase
JALSG	Japan Adult Leukemia Study Group
JCBBN	Japan Cord Blood Bank Network
JCV	JC virus
JIA	Juvenile idiopathic arthritis
JMDP	Japan Marrow Donor Program
JMML	Juvenile myelomonocytic leukemia
K15	Cytokeratin 15
KD	Kinase domain
KGF	Keratinocyte growth factor
KIR	Killer immunoglobulin-like receptor
KM	Kaplan–Meier
KPC	*Klebsiella pneumoniae* carbapenemase
KPS	Karnofsky Performance Score
KREC	Kappa-deleting recombination excision circle
LAIV	Live attenuated influenza vaccine
LAMP	Loop-mediated isothermal amplification
LAVV	Live attenuated varicella vaccine
LBL	Lymphoblastic lymphoma
LC	Langerhans cell
LCH	Langerhans cell histiocytosis
LCL	Lymphoblastic cell lines
LD	Linkage disequilibrium
LDH	Lactate dehydrogenase
LEDGF	Lens epithelium-derived growth factor
LenDex	Lenalidomide, dexamethasone
LET	Linear energy transfer
LFA	Leukocyte function-associated antigen
LFR	Limited field radiation
LFS	Leukemia-free survival
LFS	Lung function score
LGL	Large granular lymphocyte
LH	Luteinizing hormone
LHRH	Luteinizing hormone-releasing hormone
LIF	Leukemia inhibitory factor
LMD	Laser microdissection
LMP	Latency membrane protein
LMWH	Low molecular weight heparin
LN	Lymph node
LOH	Loss of heterozygosity
LPHD	Lymphocyte-predominant Hodgkin disease
LPS	Lipopolysaccharide
LQ	Linear quadratic
LRD	Lower respiratory tract disease
LRP	Lipoprotein receptor-related protein
LRP	Lung resistance protein
LRR	Leucine-rich-repeat
LSD	Lyosomal storage disorders
LTC-IC	Long-term culture initiating cell
LTFU	Long-term follow-up
LT-HSC	Long-term hematopoietic stem cell
LUTS	Lower urinary tract syndrome
LV	Lenti virus
LVEF	Left ventricular ejection fraction
M protein	Monoclonal protein
MA	Myeloablative
mAb	Monoclonal antibody
MAC	Membrane attack complex
MAC	Myeloablative conditioning
MAFIA	Macrophage Fas-induced apoptosis
MALDI-TOFMS	Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry
MAP	High-dose methotrexate, cisplatin, and doxorubicin
MAPK	Mitogen-activated protein kinase
MBC	Metastatic breast cancer
MBL	Monoclonal B-cell lymphocytosis
MBP	Myelin basic protein
MCD	Minimal change disease
MCL	Mantle cell lymphoma
MCL	Mast cell leukemia
mCMV	Murine cytomegalovirus
M-CSF	Macrophage colony-stimulating factor
MCyR	Major cytogenetic response
MDASI	M.D. Anderson Symptom Inventory
mDC	Mature dendritic cells
MDex	Melphalan, dexamethasone
MDRD	Modification of Diet in Renal Disease (Study)
MDS	Myelodysplastic syndrome
MDSC	Myeloid-derived suppressor cell
MEAC	Minimum effective analgesic concentration
MEL	Melphalan
MEP	Megakaryocyte erythrocyte progenitor
mESC	Mouse embryonic stem cell
mesna	Sodium 2-mercaptoethanesulfonate
MetaEICESS	Meta European Intergroup Cooperative Ewing Sarcoma Study
MF	Mycosis fungoides
MF	Myelofibrosis
MFC	“Multiparametric” flow cytometric
MFC	Multidimensional flow cytometry
MFD	Matched family donor
MG	Myasthenia gravis
MGDF	Megakaryocyte growth and development factor
MGH	Massachusetts General Hospital
MGMT	Methylguanine methyltransferase
MGUS	Monoclonal gammopathy of undetermined significance
mHA	Minor histocompatibility antigen
mHAQ	Modified Health Assessment Questionnaire
MHC	Major histocompatibility complex
MHV	Mouse hepatitis virus
MIC	Minimum inhibitory concentration
MICA	MHC class I chain-related gene A
MIP-1	Macrophage inflammatory protein 1
MIPI	Mantle Cell Prognostic Index
MIRD	Medical internal radiation dose
MIRL	Membrane inhibitor of reactive lysis
miRNA	micro-RNA
mITT	Modified intent-to-treat
MJM	Muscle and Joint Measure
MKP	Megakaryocyte progenitor
MLC	Mixed leukocyte culture
MLD	Metachromatic leukodystrophy
MLL	Mixed leukemia lymphoma gene
MLL	Mixed lineage leukemia
MLR	Mixed leukocyte reaction
MLS	Maroteaux–Lamy syndrome
MM	Multiple myeloma
MMF	Mycophenolate mofetil
MMR	Major molecular response
MMR	Measles/mumps/rubella
MMRD	Mismatched related donor
MMUD	Mismatched unrelated donor

MNC	Mononuclear cell
MODS	Multiple-organ dysfunction syndrome
MOG	Myelin oligodendrocyte glycoprotein
MOPP	Mechlorethamine, vincristine (Oncovin), procarbazine, prednisone
MP	Melphalan, prednisone
MP	Methylprednisolone
MPA	Mycophenolic acid
MPAG	7-*O*-Mycophenolic acid glucuronide
MPAL	Mixed phenotype acute leukemia
MPB	Mobilized peripheral blood (cells)
MPFC	Multiparameter flow cytometry
MPN	Myeloproliferative neoplasm
MPP	Multipotent progenitor
MPT	Melphalan, prednisone, thalidomide
MPV	melphalan, prednisone, bortezomib (Velcade)
MRC	Medical Research Council
MRD	Minimal residual disease
MRI	Magnetic resonance imaging
m-RNA	Messenger RNA
MRP	Multidrug resistance-associated protein
MRS	Magnetic resonance spectroscopy
MRSA	Methicillin-resistant *Staphylococcus aureus*
mRSS	Modified Rodman skin score
MS	Mass spectrometry
MS	Multiple sclerosis
MSC	Mesenchymal stem cell
MSC	Mesenchymal stromal cell
MSCH	Mouse spinal cord homogenate
MSFC	Multiple sclerosis functional composite
MSI	Microsatellite instability
MSKCC	Memorial Sloan Kettering Cancer Center
MS-LCH	Multi-system Langerhans cell histiocytosis
MSSA	Methicillin-susceptible *Staphylococcus aureus*
MTD	Maximum tolerated dose
MTOR	Mammalian target of rapamycin
Mtvs	Mouse mammary tumor virus
MTX	Methotrexate
MUD	Matched unrelated donor
MV	Measles virus
MVA	Multivariate analysis
MZ	Marginal zone
NA	Nucleoside analog
NA-DP	Nucleoside analog diphosphate
NANT	New Approaches to Neuroblastoma Therapy
NAP1	North American Pulsed Field Type 1
NASH	Non-alchoholic steatohepatitis
NAT	Nucleic acid amplification test
NA-TP	Nucleoside analog triphosphate
nbmtLINK	National Bone Marrow Transplant link
NC	Nucleated cell
NCAM	Neural cell adhesion molecule
NCCN	National Comprehensive Cancer Network
NCHS	National Center for Health Statistics
NCI	National Cancer Institute
NCIC	National Cancer Institute of Canada
NCI-WG	National Cancer Institute – Working Group
nCR	Near complete response
NCR	Natural cytotoxicity receptor
NDK	Nucleotide diphosphate kinase
NE	Norepinephrine
NEMO	Nuclear factor-kappa B essential modulator
NER	Nucleotide excision repair
NF-AT	Nuclear factor of activated T cells
NFκB	Nuclear factor-kappa B
NGS	Next-generation sequencing
NHANES	National Health and Nutrition Examination Surveys
NHEJ	Non-homologous end-joining
NHL	Non-Hodgkin lymphoma
NHLBI	National Heart, Lung, and Blood Institute
NIH	National Institutes of Health
NIL	Nilotinib
NIMA	Non-inherited maternal antigen
NIPA	Non-inherited paternal antigen
NK	Natural killer (cell)
NK	Normal karyotype
NK-T	Natural killer T (cell)
NLR	Nucleotide-binding oligomerization domain leucine-rich-repeat-containing receptor
NM	Non-myeloablative
NMA	Non-myeloablative
NMDA	*N*-Methyl-D-aspartate
NMDP	National Marrow Donor Program
NMHCT	Non-myeloablative hematopoietic cell transplantation
NNRTI	Non-nucleoside reverse transcriptase inhibitor
NO	Nitric oxide
NOD	Non-obese diabetic (mouse)
NOD	Nucleotide-binding oligomerization domain
NPC	Nasopharyngeal carcinoma
NRM	Non-relapse mortality
NRS	Neurological Rating Scale
NRTI	Nucleoside reverse transcriptase inhibitor
NS	Nephrotic syndrome
NS	Noonan syndrome
NSAID	Non-steroidal anti-inflammatory drug
N-SH2	N-Terminal src-homology 2
NST	Non-myeloablative stem-cell transplantation
NT-proBNP	N-Terminal fragment of pro-brain natriuretic peptide
nTreg	Naturally occurring regulatory T (cell)
NWTS	National Wilms Tumor Study
NZB	New Zealand black
NZW	New Zealand white
OATP	Organic anion-transporting polypeptide
OCTP	Organic cation-transporting polypeptide
OFAR	Oxaliplatin, fludarabine, cytarabine, rituximab
OLD	Obstructive lung disease
ONJ	Osteonecrosis of the jaw
ONS	Oncology Nursing Society
OPA	Office of Patient Advocacy
OPG	Osteoprotegerin
OPM	Oropharyngeal mucositis
O-PRISM	Oncologic Pediatric Risk of Mortality
OR	Odds ratio
OS	Overall survival
PACT	Psychological Assessment of Candidates for Transplantation Scale
PAD	Bortezomib, adriamycin, dexamethasone
PALE	Post-transplant acute limbic encephalitis
PAM	Pretransplant assessment of mortality
PAMP	Pathogen-associated molecular pattern
PAS	Periodic acid–Schiff
PB	Peripheral blood
PBHC	Peripheral blood hematopoietic cell
PBHCT	Peripheral blood hematopoietic cell transplantation
PBL	Peripheral blood lymphocyte
PBMC	Peripheral blood mononuclear cell
PBMTC	Pediatric Blood and Marrow Transplant Consortium
PBPC	Peripheral blood progenitor cell
PBSC	Peripheral blood stem cell
PCA	Patient-controlled analgesia
PCNSL	Primary central nervous system lymphoma
PCORI	Patient-Centered Outcomes Research Institute
PCR	Polymerase chain reaction
PCR	Programmed cell renewal

PCT	Pulmonary cytolytic thrombi
PCV	Pneumococcal conjugate vaccine
PCV	Protein conjugate vaccine
PD	Programmed death
PD	Progressive disease
PDC	Plasmacytoid dendritic cell
PDE	Phosphodiesterase
PDGFA	Platelet-derived growth factor A chain
PDGFR	Platelet-derived growth factor receptor
pDLI	Preemptive donor lymphocyte infusion
PDQ	Physician Data Query
PedsQL	Pediatric Quality of Life Inventory
PEGS	Platinum, etoposide, gemcitabine, methylprednisolone
PERDS	Peri-engraftment respiratory distress syndrome
PET	Positron emission tomography
PETHEMA	Programa para el Tratamiento de Hemopatías Malignas
PFS	Progression-free survival
PFT	Pulmonary function test
PGD	Pre-implantation genetic diagnosis
P-gp	P-glycoprotein
Ph	Philadelphia (chromosome)
PH	Pulmonary hypertension
PHA	Phytohemagglutinin A
PHN	Post-herpetic neuralgia
PHQ-9	Patient Health Questionnaire-9
PI	Protease inhibitor
PI3K	Phosphatidylinositol 3-kinase
PICC	Peripherally inserted central venous catheter
PID	Primary immunodeficiency disease
PIG-A	Phosphatidylinositol glycan-A
PIP$_2$	Phosphatidylinositol 4,5-diphosphate
PIP$_3$	Phosphatidylinositol 3,4,5-triphosphate
PIQ	Performance IQ
PJP	*Pneumocystis jirovecii* pneumonia
PK	Pharmacokinetic
PKC	Protein kinase C
PlGF	Placental growth factor
PLL	Prolymphocytic leukemia
PLP	Proteolipid protein
PLPHA	Postlumbar puncture headache
PMC	Persistent mixed chimerism
PMF	Primary myelofibrosis
PMGCT	Primary mediastinal germ-cell tumor
PML	Progressive multifocal leukoencephalopathy
PMN	Polymorphonuclear neutrophil
PN	Parenteral nutrition
PN	Peripheral neuropathy
PNET	Primitive neuroectodermal tumor
PNH	Paroxysmal nocturnal hemoglobinuria
PNH-sc	Subclinical paroxysmal nocturnal hemoglobinuria
POEMS	Polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes
POF	Premature ovarian failure
POG	Pediatric Oncology Group
POLST	Physician Orders for Life Sustaining Treatment
PomDex	Pomalidomide, dexamethasone
PORN	Progressive outer retinal necrosis
PORT	Patient Outcomes Assessment Research Team
PPI	Proton pump inhibitor
PR	Partial remission or partial response
PR	Progesterone receptor
PR3	Proteinase 3
PRCA	Pure red cell aplasia
PRES	Posterior reversible encephalopathy syndrome
PRO	Patient-reported outcome
PROMIS	Patient-Reported Outcomes Measurement Information System

PRR	Pathogen recognition receptor
PRST	Pediatric Registry for Stem Cell Transplantations
PSA	Prostate-specific antigen
PSC	Pluripotent stem cell
PSE	Prednisone
PSQI	Pittsburgh Sleep Quality Index
PT	Pertussis toxoid
PTA	Peripheral tissue antigen
PTCL	Peripheral T-cell lymphoma
PTCL-nos	Peripheral T-cell lymphoma not otherwise specified
PTH	Parathyroid hormone
PTLD	Post-transplant lymphoproliferative disorder
PTPase	Protein tyrosine phosphatase
PUVA	Psoralen–ultraviolet A irradiation (treatment)
PV	Polycythemia vera
PVR	Polio virus receptor
PyVAN	Polyomavirus-associated nephropathy
PyVHC	Polyomavirus-associated hemorrhagic cystitis
QALY	Quality-adjusted life-year
QLQ	Quality of Life Questionnaire
QOL	Quality of life
qRT-PCR	Quantitative reverse transcription polymerase chain reaction
QTL	Quantitative trait loci
QW	Once weekly
RA	Refractory anemia
RA	Retinoic acid
RA	Rheumatoid arthritis
RA	Right atrium
RAb	Radiolabeled antibody
RAEB	Refractory anemia with excess blasts
RAEB-T	Refractory anemia with excess blasts in transformation
RANKL	Receptor activator of nuclear factor **k**appa B ligand
RARS	Refractory anemia with ringed sideroblasts
RBC	Red blood cell
RCC	Ratio of costs to charges
RCC	Refractory cytopenia of childhood
RCC	Renal cell carcinoma
R-CHOP	Rituximab, cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone
RCMD	Refractory cytopenia with multilineage dysplasia
RCR	Replication competent retrovirus
RCT	Randomized controlled trial
REAL	Revised European–American Lymphoma
R-EPOCH	Rituximab, etoposide, prednisone, vincristine (Oncovin), doxorubicin hydrochloride
RES	Reticuloendothelial system
R-ESHAP	Rituximab, etoposide, cytarabine, cisplatin, methylprednisolone
RFS	Relapse-free survival
Rh	Rhesus
rHBV	Recombinant hepatitis B vaccine
RHC	Residual host cells
rhGH	Recombinant human growth hormone
r-hIL-7	Recombinant human interleukin-7
rHuEPO	Recombinant human erythropoietin
R-hyperCVAD	RTX (rituximab), vincristine, doxorubicin, dexamethasone
RI	Relapse incidence
RIC	Reduced-intensity conditioning
RICR	Reduced-intensity conditioning regimen
RIFLE	Risk, injury, failure, loss, end-stage
RISC	RNAi-induced silencing complex
RIT	Radioimmunotherapy
RLD	Restrictive lung disease
RLR	Rig-1-like receptor
RN	Registered nurse

RNAi	RNA interference
RNR	Ribonucleotide reductase
ROC	Receiver-operating characteristic
ROS	Reactive oxygen species
RR	Relapse rate
RR	Relative risk
RR	Response rate
RRE	Rev response element
RRE	Risk ratio estimate
RRMS	Relapsing–remitting multiple sclerosis
RRT	Regimen-related toxicity
RSCH	Rat spinal cord homogenate
RSCL	Rotterdam Symptom Checklist
RSV	Respiratory syncytial virus
RT	Reverse transcriptase
RTE	Recent thymic emigrant
RTID	Respiratory tract infectious disease
RT-PCR	Real-time polymerase chain reaction
RTQ	Real-time quantitative
RTX	Rituximab
RVD	Revlimid/lenalidomide, Velcade/bortezomib, dexamethasone
S1P	Sphingosine-1 phosphate
SAA	Serum amyloid A
SAA	Severe aplastic anemia
SAAG	Serum-ascites albumin gradient
SAHA	Suberoylanilide hydroxamic acid
SAP	Serum amyloid protein P
SARS	Severe acute respiratory syndrome
SAS-SR	Social Adjustment Scale – Self Report
SBT	Sequence-based typing
SCC	Squamous cell carcinoma
SCD	Sickle cell disease
SCF	Stem-cell factor
scFv	Single-chain variable fragment
SCID	Severe combined immunodeficiency syndrome
SCID-hu	Severe combined immunodeficiency syndrome/human (mouse)
SCL	Stem-cell leukemia
SCT	Stem-cell transplantation
SCTOD	Stem Cell Therapeutics Outcomes Database
SD	Stable disease
SD	Standard deviation
SDC	Standard-dose chemotherapy
SDF	Stroma cell-derived factor
SDS	Shwachman–Diamond syndrome
SE	Standard error
SEC	Sinusoidal endothelial cell
SEER	Surveillance Epidemiology and End Results
Sema	Semaphorin
SEREX	Serological identification of antigens by recombinant expression cloning
SERM	Selective estrogen response modulator
SF-36	Medical Outcomes Study Short Form 36
SFGM	Société Française de Greffe de Moelle
SFK	SRC-family kinase
SFOP	Société Française de l'Oncologie Pédiatrique, French Society of Pediatric Oncology
SFQ	Sexual Function Questionnaire
SGOT	Serum glutamic-oxaloacetic transaminase
SHBG	Sex hormone-binding globulin
SHEA	Society for Healthcare Epidemiology of America
Shh	Sonic hedgehog
SHM	Somatically hypermutated
SI	Stimulation index
SIADH	Syndrome of inappropriate antidiuretic hormone
SIG	Special Interest Group
sIgm	Cell surface immunoglobulin M
siRNA	Short interfering RNA
SJS	Stevens–Johnson syndrome
SKD	Severe keratinocyte dysplasia
SLAM	Signaling lymphocyte activation molecule
SLD	Sublethal damage
SLE	Systemic lupus erythematosus
SLEDAI	SLE Disease Activity Index
SM	Systemic mastocytosis
SMILE	Ddexamethasone, methotrexate, ifosfamide, L-asparaginase, etoposide
SMN	Subsequent malignant neoplasm
SMR	Standardized mortality ratio
SNP	Single nucleotide polymorphism
SNRI	Serotonin–norepinephrine reuptake inhibitor
SNS	Sympathetic nervous system
SOFA	Sequential (or sepsis-related) Organ Failure Score
SOP	Standard operating procedure
SOS	Sinusoidal obstruction syndrome
SOT	Solid organ transplantation
SP	Surfactant protein
SPECT	Single photon emission computed tomography
SR	Sensitive relapse
SR	Standard risk
SS	Sézary syndrome
SSA	Sex steroid ablation
SSA	Single-strand annealing
SSc	Systemic sclerosis
SSD	Source-to-skin distance
SSOP	Sequence-specific oligonucleotide probe
SSP	Sequence-specific primer
SSRI	Selective serotonin reuptake inhibitor
SST	Short Syntachten Test
STAMP-I	Cyclophosphamide, cisplatin, BCNU
STAMP-V	Cyclophosphamide, carboplatin, thioTEPA
STATs	Signal transducers and activators of transcription
STBI	Single-fraction total body irradiation
ST-HSC	Short-term hematopoietic stem cell
STING	Stimulator of interferon genes
STR	Short tandem repeat
SVC	Superior vena cava
SWOG	Southwest Oncology Group
T1DM	Type 1 diabetes mellitus
T3	Triiodothyronine
T4	Thyroxine
TAA	Tumor-associated antigen
TAAM	Time-averaged mean of the maximum
TACL	Therapeutic Advances in Childhood Leukemia
TAD	Thalidomide, adriamycin, dexamethasone
TA-GVHD	Transfusion-associated graft-versus-host disease
TAI	Thoracoabdominal irradiation
TAM	Transplant-associated microangiopathy
t-AML	Therapy-related acute myeloid leukemia
TAP	Transporter associated with antigen processing
TAR	Tat response element
TBI	Total body irradiation
TCA	Tricyclic antidepressant
TCD	T-cell depletion
TCD	Transcranial Doppler (ultrasonography)
TCE	T-cell epitope
T_{CM}	Central memory T (cells)
Tcon	Conventional T
TCR	T-cell receptor
TD	Thalidomide, dexamethasone
TDM	Therapeutic drug monitoring
TdT	Terminal deoxynucleotidyl transferase
TED	Thromboembolic disease
T_{EM}	Effector memory T (cell)
TEN	Toxic epidermal necrolysis

TEPA	*N*-Triethylenephosphoramide
TEPC	Thymic epithelial progenitor cell
TERS	Transplant Evaluation Rating Scale
TERT	Telomerase reverse transcriptase
TF	Tissue factor
T_{FH}	T follicular helper
TFIIH	Transcription factor IIH complex
TFPI	Tissue factor pathway inhibitor
TG	Triglyceride
TGF-β	Transforming growth factor beta
T-GVHD	Transfusion-associated graft-versus-host disease
TH	Helper T-lymphocytes
T_H	T helper
thioTEPA	*N*-Triethylenethiophosphoramide
TICE	Paclitaxel, ifosfamide followed by high-dose carboplatin, etoposide
TIL	Tumor-infiltrating lymphocytes
TIP	Paclitaxel, ifosfamide, cisplatin
TIV	Trivalent influenza vaccine
TK	Thymidine kinase
TKI	Tyrosine kinase inhibitor
TLC	Total lung capacity
TLI	Total lymphoid irradiation
TLR	Toll-like receptor
TLS	Tumor lysis syndrome
TM	Thalassemia major
TMA	Thrombotic microangiopathy
TMD	Temporomandibular dysfunction
t-MDS	Therapy-related myelodysplastic syndrome
TMEV	Theiler's murine encephalomyelitis virus
TMI	Total marrow irradiation
TMLI	Total marrow and lymphoid irradiation
TMP–SMX	Trimethoprim–sulfamethoxazole
TM–SLF	Trimethoprim–sulfamethoxazole
TNC	Total nucleated cell
TNF	Tumor necrosis factor
TNFR	Tumor necrosis factor receptor
TNF-α	Tumor necrosis factor α
TOI	Trial Outcome Index
TPA	Tissue plasminogen activator
T-PLL	T-cell prolymphocytic leukemia
TPN	Total parenteral nutrition
TPO	Thrombopoietin
TR	Tandem repeat
TRAIL	TNF-related apoptosis-inducing ligand
TRALI	Transfusion-related acute lung injury
TREC	T-cell receptor excision circles
Treg	Regulatory T (cell)
Treo	Treosulfan
TRM	Transplant-related mortality
TRT	Testosterone replacement therapy
TRV	Tricuspid regurgitation velocity
TSH	Thyroid-stimulating hormone
TSLP	Thymic stromal lymphoietin
TT	*N*-Triethylenethiophosphoramide, thioTEPA
TTP	Thrombotic thrombocytopenic purpura
TTR	Transthyretin
UBC	Umbilical cord
UCB	Umbilical cord blood
UCB	Unrelated cord blood
UCBT	Umbilical cord blood transplant
UGT	Uridine 5′-diphosphate glucuronosyltransferase
UPD	Uniparental disomy
URD	Unrelated donor
URI	Upper respiratory tract infection
UV	Ultraviolet
VAD	Vincristine, adriamycin, dexamethasone
VATS	Video-assisted thoracoscopic surgery
VBAD	Vincristine, BCNU, doxorubicin, dexamethasone
VBMCP	Vincristine, BCNU, melphalan, cyclophosphamide, prednisone
VCD	Velcade/bortezomib, cyclophosphamide, dexamethasone
VDCR	Velcade/bortezomib, dexamethasone, cyclophosphamide, Revlimid/lenalidomide
VDR	Vitamin D receptor
VE	Vascular endothelial
VEGF	Vascular endothelial growth factor
VeIP	Vinblastine, ifosfamide, cisplatin
VF	Ventricular fibrillation
VGPR	Very good partial remission
VIC	Virus isolation by cell culture
VIP	Etoposide, ifosfamide, cisplatin
VIP	Vasoactive intestinal peptide
VISA	Vancomycin-intermediate *Staphylococcus aureus*
VLCFA	Very long-chain fatty acid
VNTR	Variable number of tandem repeat
VOD	Veno-occlusive disease
VRE	Vancomycin-resistant *Enterococcus*
VSAA	Very severe aplastic anemia
VT	Ventricular tachycardia
VTD	Velcade/bortezomib, thalidomide, dexamethasone
vWF	von Willebrand factor
VWMD	Vanishing white matter disease
VZIG	Varicella zoster immune globulin
VZV	Varicella zoster virus
WAS	Wiskott–Aldrich syndrome
WBC	White blood cell
WBM	Whole bone marrow
WBMT	Worldwide Network for Blood & Marrow Transplantation
WBRT	Whole-brain radiotherapy
WES	Whole exome sequencing
WGA	Wheat germ agglutinin
WGS	Whole genome sequencing
WMDA	World Marrow Donor Association
WNV	West Nile virus
WPSS	WHO classification-based Prognostic Scoring System
WSG	West German Study Group
wt	Wild-type
X-ALD	X-linked adrenoleukodystrophy
XRT	External-beam radiotherapy
YFC	[^{90}Y]ibritumomab tiuxetan, fludarabine, cyclophosphamide
ZAP-70	Zeta-associated protein
ZFN	Zinc finger nuclease
ZIG	Zoster immune globulin
ZIP	Zoster immune plasma

CHAPTER 56

Hematopoietic Cell Transplantation for Hodgkin Disease

Philip J. Bierman[1] **and Auayporn Nademanee**[2]
[1] University of Nebraska Medical Center, Omaha, NE, USA
[2] City of Hope Medical Center, Duarte, CA, USA

Epidemiology and etiology

Hodgkin disease (HD) is a clonal lymphoid disorder of mononuclear Hodgkin cells and multinucleated Reed–Sternberg cells, which are considered to be derived from germinal center B cells [1]. In 2013, it was estimated that there would be 9290 new cases of HD in the United States and that 1180 people would die with this diagnosis [2]. Between 2000 and 2004, the HD incidence rate in the United States was 2.7 per 100,000 [3], and this incidence rate has been stable in recent years. There is a bimodal incidence with one peak in the late teen years and early adulthood, and a second peak that is seen in adults after age 50 years. The incidence rate for HD is higher in men, and higher in Whites than in Blacks, Asians, and Hispanics.

The risk factors associated with HD are not as consistent or well understood as those identified for non-Hodgkin lymphoma. Reed–Sternberg cells often express Epstein–Barr virus (EBV)-associated antigens. The HD incidence rate is higher in patients who have had infectious mononucleosis, although links between EBV and HD are inconsistent. Patients infected with HIV are more likely to develop HD, and HD has been described following solid organ transplantation. Some studies have shown a slight familial risk associated with HD, and there appears to be a higher risk in monozygotic twins of affected individuals.

Molecular and clinical biology

The World Health Organization (WHO) classification divides Hodgkin disease into two entities that have different clinical and biologic characteristics [1]. Approximately 5% of cases are classified as nodular lymphocyte predominant Hodgkin lymphoma (nodular LPHD), which is characterized by neoplastic cells known as popcorn or L&H (lymphocytic and/or histiocytic) cells. The neoplastic cells almost always express CD20. Most patients have classical Hodgkin lymphoma, which is subdivided into nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted subtypes. The neoplastic Reed–Sternberg cells within classical HD subtypes usually express CD30, and often CD15.

Hodgkin cells release a variety of cytokines, including various interleukins. This may explain the inflammatory background seen in HD biopsies and explain eosinophilia and some systemic symptoms seen in HD, and also fibrosis seen in biopsies. No consistent cytogenetic abnormalities are seen in HD, although immunoglobulin gene rearrangements are characteristic. No consistent environmental causes of HD have been identified, although some studies have identified increased risk associated with woodworking.

Clinical description

The most common HD symptom is painless lymphadenopathy. The disease spreads contiguously and patients may have localized or widespread disease. Mediastinal involvement is most common in the nodular sclerosis subtype. Extranodal disease is less common than in non-Hodgkin lymphoma (NHL). Patients may have systemic or "B" symptoms consisting of unexplained fevers, night sweats, or weight loss. Pruritus may be seen and precede the diagnosis of HD for months.

Approximately 70% of patients with nodular LPHD are males in the age range 30–50 years. Patients often have localized disease, and may have an indolent disease course. The most common subtype of classical HD is nodular sclerosis, which is more likely to be present in patients with limited-stage disease. The mixed cellularity subtype is more likely to be found in patients with immunodeficiency syndromes.

Non-transplant approaches

More than 50% of HD patients, including those with advanced disease, can be cured with a wide variety of chemotherapy regimens [4,5]. This accomplishment is one of the greatest achievements of modern medicine. There has been a dramatic decline in HD mortality and the 5-year survival rate is now approximately 85%.

In the past, limited-stage HD was usually treated with radiation therapy. Limited radiation may be used for low-stage nodular LPHD. However, concerns about late toxicity associated with extensive radiation fields have led to the common practice of using abbreviated courses of chemotherapy followed by involved-field radiation for most patients. In some cases, chemotherapy alone may be used. Patients with advanced disease or bulky masses are treated with a full course of chemotherapy and sometimes receive additional radiotherapy. A major focus of new treatment regimens involves the reduction of late toxicities of HD treatment.

Although most patients with HD are cured with initial therapy, a significant proportion still fail to attain a complete remission or

relapse after attaining a remission. A variety of conventional-dose second-line (salvage) regimens have been used for these patients, but results of treatment with these regimens are disappointing and few patients achieve long-term disease-free survival (DFS).

Hematopoietic cell transplantation

The poor results of conventional-dose salvage therapy for relapsed and refractory HD have led to the use of high-dose therapy (HDT) followed by autologous bone marrow transplantation (BMT) and peripheral blood hematopoietic cell transplantation (PBHCT) for these patients. This approach is based upon the steep dose–response curves exhibited by several drugs, and also radiation therapy, and the fact that dose-limiting toxicities are often related to myelosuppression. The first attempts at using autologous bone marrow infusions to reduce myelosuppression following radiation and chemotherapy were documented in the 1950s. Later, techniques for bone marrow harvesting and cryopreservation were refined and results of autologous BMT for HD began to be reported [6].

Since then, the use of HDT followed by autologous hematopoietic cell transplantation (aHCT) for HD has increased dramatically and this approach has become accepted therapy in a variety of circumstances. In North America, HD is the third most common indication for aHCT after multiple myeloma and NHL. Approximately 1200 aHCTs for HD were reported to the Center for International Blood and Marrow Transplant Research (CIBMTR) in 2009 [7]. It is estimated that this total represents approximately 60% of the transplants being performed for this indication in North and South America. Results from the European Group for Blood and Marrow Transplantation (EBMT) are similar [8]. HD is the third most common indication for aHCT in Europe, and it was reported that 1677 aHCTs for HD were performed there during 2005.

Autologous HCT has become easier, safer, and less expensive over the last 25 years. Mortality within 100 days of transplant is generally under 5% and improved outcomes over time have been demonstrated [7,9]. These improvements are due to increased experience at individual institutions, improved patient selection, the routine use of hematopoietic growth factors, and the increased use of autologous PBHCT, as compared with autologous BMT. aHCT is commonly performed by community oncologists and can be performed on elderly patients, in the outpatient setting [10], and in patients with religious objections to blood transfusion [11].

Results of autologous hematopoietic cell transplantation

The results of some of the larger and most recent series of aHCT for HD are displayed in Table 56.1. It is difficult to compare results because of differences in selection criteria, patient characteristics, HDT regimens, and supportive care. In addition, the length of follow-up varies considerably and some reports include patients transplanted before the routine use of autologous PBHCT and hematopoietic growth factors. Nevertheless, these results demonstrate that a significant proportion of patients achieve long-term progression-free survival (PFS) following transplantation, and that transplantation can be accomplished with low early mortality. It is unknown whether the use of more aggressive and more effective primary chemotherapy regimens will alter the results of transplantation for patients who require salvage therapy [4].

Representative results of HDT followed by aHCT for a large group of patients with relapsed and refractory HD with long follow-up are displayed in Figure 56.1. The results of aHCT for patients with relapsed and refractory HD appear better than those reported with conventional-dose salvage chemotherapy.

Randomized trials

Two randomized trials have compared the results of conventional-dose salvage chemotherapy with aHCT for relapsed and refractory HD. A British National Lymphoma Investigation (BNLI) trial randomized patients with relapsed and refractory HD to receive treatment with mini-BEAM [BCNU = 1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine), etoposide, Ara-C = cytarabine (cytosine arabinoside), melphalan] conventional-dose salvage chemotherapy, or treatment with BEAM (same drugs at higher doses) followed by autologous BMT (aBMT) [12]. This study design tested the role of dose intensity

in the treatment of HD since the same drugs were used in each treatment arm. The 3-year event-free survival (EFS) was estimated to be 53% in transplanted patients, compared with 10% in the mini-BEAM group (Figure 56.2). The risk of disease progression was also significantly lower in transplanted patients, although no significant differences in overall survival (OS) were observed. Some participants preferred treatment with aBMT and refused randomization, and the study was terminated early.

The German Hodgkin Study Group (GHSG) and the EBMT conducted the other randomized trial, which also closed early because of poor accrual [13]. After randomization, patients received two courses of salvage chemotherapy with Dexa-BEAM (dexamethasone, carmustine, etoposide, cytarabine, melphalan). Responding patients received either two additional courses of Dexa-BEAM, or else high-dose BEAM followed by aHCT. The freedom from treatment failure at 3 years was estimated to be 55% for patients treated with aHCT, compared with 34% for those who received Dexa-BEAM, alone (Figure 56.3). OS rates were estimated to be 71 and 65%, respectively ($p = 0.331$).

Non-randomized trials

Several non-randomized trials have compared the results of conventional salvage chemotherapy with results of aHCT for patients with relapsed and refractory HD. A French registry analysis examined outcomes in patients who failed to respond to treatment or progressed after treatment with a single chemotherapy regimen [14]. The 5-year OS was estimated to be 71% for patients who received aHCT, compared with 32% for others ($p = 0.0001$). Freedom from treatment failure was estimated to be 60 and 20%, respectively ($p = 0.0001$). A multivariate analysis showed that salvage treatment that did not include HDT was associated with significantly worse OS ($p = 0.02$) and freedom from treatment failure ($p = 0.02$). Additional trials discussed in later sections include retrospective registry analyses after first relapse [15], single-institution studies of patients with refractory and relapsed disease [16], and registry analyses of patients with primary refractory disease [14,17,18].

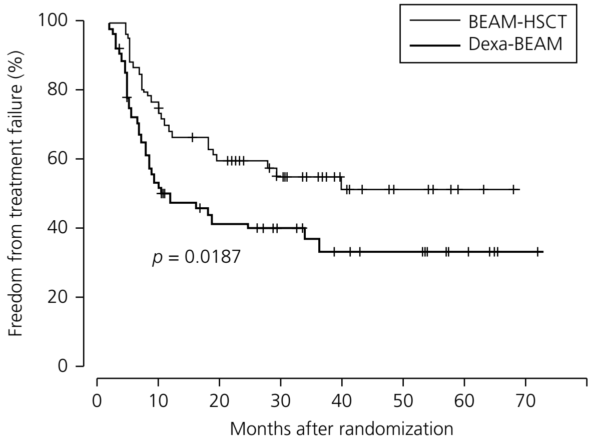
Prognostic factors

A large number of factors have been identified that are associated with adverse outcomes for patients who undergo aHCT for HD. Several prognostic models have been developed that use these factors to predict outcome following transplantation. The Vancouver group examined patients undergoing aBMT for HD in first relapse [19]. The presence of systemic symptoms at relapse, extranodal disease at relapse, and initial remission duration less than 12 months were associated with shorter PFS. The 3-year PFS was 100, 81, 40,



Number of patients

and 0% for patients with no, one, two, or three risk factors, respectively. Investigators from Memorial Sloan Kettering Cancer Center (MSKCC) found that the same three factors were significant when applied at the time patients received conventional salvage chemotherapy prior to aHCT [20]. The EFS was estimated to be 83% for those with no or one risk factor, 27% for those with two risk factors, and 10% for patients with all three risk factors ($p < 0.001$). The OS rates were 90, 57, and 25%, respectively ($p < 0.001$).

A model for patients transplanted with relapsed or refractory HD was developed at Stanford University [21]. Bone marrow or pulmonary involvement, systemic symptoms at relapse, and more than minimal disease at transplant (>75% reduction in a bulky mass or no nodes >2cm and <10% marrow involvement) were associated with significantly worse OS, EFS, and freedom from progression. Actuarial freedom from progression at 3 years was estimated to be 85, 57, 41, and <20% for patients with no, one, two, and three risk factors, respectively ($p = 0.0001$).

Another model developed in Boston used progressive disease at the time of HCT, more than one extranodal site of relapse, and poor performance status, to construct a prognostic index [22]. The 3-year actuarial survival was 82, 56, and 19% for patients with no, one, or two or more risk factors, respectively ($p = 0.0001$).

A French registry analysis evaluated results of aHCT for relapsed HD [18]. The presence of extranodal disease at relapse and initial remission duration under 12 months were identified as significant risk factors. The 4-year OS was estimated to be 93, 59, and 43%, for patients with no, one, or two risk factors, respectively.

A GHSG study evaluated patients with relapsed HD and determined that initial remission duration less than 12 months, stage III or IV disease at relapse, and anemia at relapse could be used to construct a prognostic model for patients treated with aHCT [18]. An index based upon the presence of no, one, two, or three of these risk factors was able to identify groups with significantly different rates of survival ($p < 0.0001$).

At the University of Nebraska, a prognostic index was developed based upon factors used in the International Prognostic Factors Project Score for advanced HD [5,23]. Low serum albumin (<4g/dL), anemia (<10.5g/dL), age (≥45 years), and lymphocytopenia (<600/mm^3 and/or <8% of total white blood cell count) were associated with inferior outcomes. The estimated 10-year OS rates were 48, 35, 27, and 20%, for patients with no, one, two, or three or more risk factors, respectively.

Another prognostic model was developed at the University of Minnesota [24]. Absence of systemic symptoms at the time of transplant, transplantation in complete remission, and chemotherapy-sensitive disease were independent predictors of improved PFS. The 5-year predicted PFS was 67, 37, and 9% for those with no or one, two, or three risk factors, respectively ($p < 0.001$).

The influence of histologic subtype has not been extensively studied, although one study showed that patients with lymphocyte-predominant histology had significantly longer EFS than other patients [25]. The use of [^{18}F]fluorodeoxyglucose positron emission tomography (FDG-PET) scans has been shown to be useful in the management of HD and NHL. Several studies have evaluated the importance of FDG-PET scans performed prior to aHCT for HD and found that a negative FDG-PET scan is associated with improved PFS [26].

The most important risk factors associated with adverse outcome following aHCT for HD are displayed in Table 56.2. It should be noted that some of these prognostic factors have not been shown to be important in all studies. This is likely related to differences in patient characteristics, selection bias, and sample size. Nevertheless, most studies show that extensive therapy prior to transplant, poor performance status, chemotherapy resistance, and active disease at the time of transplant are predictive of poorer outcome after aHCT for HD.

Pre-transplant "debulking" chemotherapy

Almost all patients with relapsed NHL are treated with conventional-dose salvage chemotherapy to reduce tumor burden prior to treatment with HDT and aHCT. Sensitivity to pre-transplant salvage therapy is one of the most important prognostic factors for PFS and OS following aHCT. The majority of patients with relapsed HD are also treated in this manner and most studies show that chemotherapy sensitivity is an important prognostic factor for these patients, also (Table 56.2). A wide variety of chemotherapy regimens have been used for this purpose, although the ICE (ifosfamide, carboplatin, etoposide) regimen has become popular [20].

The potential impact of administering pre-transplant salvage chemotherapy was evaluated in a study by the Autologous Blood and Marrow Transplant Registry (ABMTR) that compared outcomes of HD patients in first relapse with those in second remission [27]. The actuarial 3-year OS was 58% for patients who received aHCT in first relapse, compared with 75% for patients transplanted in second complete remission ($p < 0.001$).

The Polish Transplant Group showed that actuarial 5-year EFS was 16% for HD transplanted with active disease, compared with 66% for patients in complete remission ($p < 0.001$) [25]. At the University of Rochester, the 5-year EFS was projected to be 46% for patients with minimal disease (all areas ≤2cm) at the time of transplant, compared with 10% for those with bulky disease ($p = 0.0002$) [28]. Autologous HCT results from the Grupo Español de Linfomas/Trasplante Autólogo de Médula Ósea (GEL/TAMO) Spanish cooperative group revealed that the actuarial time to treatment failure was 63.2% at 5 years following HCT for HD patients transplanted in complete remission, compared with 32.2% for those with measurable disease ($p = 0.00001$) [9]. In this cohort, the 5-year time to treatment failure was estimated to be 32.6% for patients transplanted

Table 56.2 Adverse prognostic factors: autologous hematopoietic cell transplantation for Hodgkin disease

Prognostic factor	Ref.
Bulky or "non-minimal" disease at transplant	[12,13,16,19,29,30]

Anemia at relapse or transplant	[40]
Hypoalbuminemia at transplant	[40]

with bulky disease, compared with 45.8% for others ($p = 0.045$). At Toronto, the 4-year actuarial DFS was 68% for HD patients who had no evidence of disease at the time of transplant, 26% for patients transplanted with non-bulky disease, and 0% for those with bulky disease ($p = 0.0002$) [29]. At Stanford University, the presence of more than minimal disease (see above) at the time of transplant was associated with significantly worse PFS, EFS, and OS [21]. The Minnesota group showed that relapsed and refractory HD patients who underwent aHCT with residual disease present had a 2.3-fold relative risk of progressive disease compared with those who were transplanted while free of disease ($p = 0.03$) [24]. A similar Cleveland Clinic analysis demonstrated that HD patients transplanted with bulky disease (>10cm) had significantly poorer survival than other patients (hazard ratio 2.9, $p = 0.002$) [30].

These results suggest that treatment with conventional salvage chemotherapy to reduce tumor burden prior to aHCT improves outcomes. However, the absence of bulk may be a surrogate for chemotherapy sensitivity, and some patients might do well without additional therapy prior to transplant. In addition, some patients with relapsed and refractory HD fail to respond to conventional salvage therapy and never proceed to transplantation. For these reasons, a comprehensive two-step transplant regimen was developed at MSKCC so that all patients with relapsed and refractory HD could be evaluated on an intent-to-treat basis [20]. This program consists of two cycles of ICE conventional salvage therapy, followed by accelerated fractionation involved-field radiation, and then HDT and aHCT. The rate of response to ICE was 88%, and the OS and EFS at a median of 43 months were projected to be 73 and 58%, respectively, for all patients. The OS and EFS for the 86% of patients who proceeded to aHCT were 83 and 68%, respectively. This type of intent-to-treat analysis gives a more realistic assessment of the role of transplantation for HD.

The use of pre-transplant chemotherapy may not be necessary in all circumstances. At University College Hospital in London, the actuarial 5-year PFS was 78% in a cohort of patients with HD who underwent aHCT in "untested" relapse [13]. The 5-year PFS was estimated to be 57% for HD patients in the Spanish registry who were transplanted in untested relapse [9]. At the University of Nebraska, the 5-year OS was estimated to be 100% for HD patients who were transplanted without additional therapy after relapse, compared with 45% for patients who received conventional chemotherapy prior to aHCT ($p = 0.048$) [31]. An EBMT retrospective analysis showed no significant differences in OS or PFS when HD patients in untested relapse were compared with those who received conventional salvage therapy prior to aHCT [32].

Patients with HD who are transplanted without conventional salvage chemotherapy may do well because they have minimal tumor burden at the time of relapse. Nevertheless, pre-transplant debulking chemotherapy may not be necessary for all HD patients and it may be possible to eliminate this treatment for patients with minimal tumor burden at the time of relapse, or those without evidence of disease after the site of relapse is resected. Most patients, however, would benefit from pre-transplant chemotherapy, particularly those who have significant tumor burdens.

Pre-transplant radiation therapy

Radiation is an essential tool in the treatment of HD. At some institutions, radiotherapy is used instead of chemotherapy or in addition to chemotherapy to reduce tumor burden prior to aHCT, whereas other institutions administer radiation as consolidation therapy after transplant (see below). There are several unanswered questions regarding the potential advantages and disadvantages of each approach.

The use of radiotherapy prior to transplant can reduce tumor burden and usually does not delay the start of HDT. Multiple institutions have used pre-transplant involved-field radiation for patients undergoing aHCT for HD [21,29,33–37]. Although this may improve local control and decrease the incidence of relapse in irradiated areas, it has been difficult to demonstrate definite survival advantages associated with this therapy [33–35]. At MSKCC, patients with relapsed and refractory HD are treated with an integrated approach utilizing conventional salvage chemotherapy, 1800–3600cGy accelerated fractionation involved-field radiation administered twice daily over a 5–10-day period, followed by aHCT [20].

Pre-transplant involved-field radiation may be associated with increased post-transplant complications such as esophagitis and pulmonary toxicity, especially after mediastinal irradiation. An analysis at the University of California Los Angeles demonstrated that radiation prior to aHCT [using a total body irradiation (TBI)-containing regimen] for HD is associated with significantly higher morbidity and mortality compared with post-transplant radiation [38]. Similar analyses conducted for patients with NHL suggest that pre-transplant radiotherapy may be associated with an increased risk of secondary myelodysplasia or respiratory complications [34]. Hence pre-transplant radiotherapy should be used with caution, especially when high-dose carmustine is given after mediastinal irradiation.

Post-transplant therapy

A number of approaches have been utilized to decrease the risk of relapse following aHCT for HD. At many institutions, involved-field radiation is used following aHCT as consolidation therapy or to treat areas of persistent disease [13,14,24,28,39,40]. Delaying radiation until after aHCT may decrease the incidence of transplant-related complications and may avoid delays in starting HDT due to toxicities of pre-transplant radiation. Post-transplant irradiation can convert a partial remission into a durable complete remission [41].

A retrospective analysis by the University of Rochester demonstrated that actuarial 5-year EFS was 44% for HD patients who received post-transplant consolidative radiotherapy, compared with 26% for patients who did not receive radiation ($p = 0.0056$) [28]. A retrospective analysis by the University of Maryland also demonstrated significantly improved EFS among HD patients who received additional radiotherapy following aHCT [42]. Potential advantages attributed to post-transplant radiation therapy have been seen in other analyses, although randomized trials have not been conducted [35]. Issues relating to selection bias make it difficult to evaluate the advantages of involved-field radiation therapy following aHCT for HD, because patients with early relapse, poor performance status, and delayed engraftment may not be able to be treated. In addition, the use of radiation with primary therapy makes many patients ineligible for additional radiotherapy. Post-transplant radiation may also lead to significant hematologic and non-hematologic toxicity and it is unclear whether it is more advantageous to administer the radiation prior to aHCT. There are also other unresolved issues related to the timing and schedule of treatment, treatment fields, and radiation dose.

In addition to post-transplant involved-field radiation therapy, several groups have conducted phase I/II trials with interferon, interleukin-2 (IL-2), and IL-2 with lymphokine-activated killer cells to decrease relapse rates after aHCT for HD [43,44]. A retrospective analysis by the Polish Lymphoma Research Group suggested that the use of immunotherapy following aHCT for primary refractory HD was associated with significantly better PFS and OS [44]. Although the use of post-transplant immune modulation is feasible and augmentation of various parameters of immune function can be demonstrated, there have been no studies that conclusively show a benefit from this approach.

A number of other approaches have been used to decrease relapse rates following aHCT for HD. Investigators in Baltimore used consolidation chemotherapy administered at 3, 6, 9, and 12 months after transplant [42]. Perhaps the most aggressive form of post-transplant therapy involves the use of a planned second transplant. The group at Valhalla, NY, performed tandem transplants with a regimen containing thioTEPA (*N*-triethylenethiophosphoramide), mitoxantrone, and carboplatin for the first transplant, and ifosfamide, carboplatin, and etoposide for the second [45]. An HD tandem transplant protocol developed at the City of Hope utilized melphalan for the first transplant and TBI or carmustine, combined with etoposide and cyclophosphamide, for the second [46]. Given the efficacy of brentuximab vedotin as salvage therapy for patients with HD relapsing after aHCT [47], a phase III randomized study showed that early consolidation with brentuximab vedotin after aHCT improved PFS in HD patients with risk factors for relapse or progression. Median PFS was 43 months for brentuximab vedotin group compared with 24 months for placebo group [48].

Functional imaging

Positron emission tomography using FDG-PET has been used to assess response to therapy and it is now included in the standard response criteria for lymphoma. FDG-PET has also been shown to provide prognostic information at interim analysis during front-line therapy [49] as well as prior to aHCT in HD patients [49]. A retrospective study from the M.D. Anderson Cancer Center showed that positive FDG-PET before aHCT was predictive of poor outcome with 3-year OS of 58% compared with 87% for FDG-PET negative [50]. Investigators at MSKCC reported that FDG-PET status before aHCT was the only factor significant for EFS and OS in 153 relapsed/refractory HD patients with chemosensitive disease after ICE salvage therapy and before aHCT. The 5-year EFS was 31% for FDG-PET-positive compared with 75% for FDG-PET-negative patients [51] (Figure 56.4). The administration of involved-field radiotherapy with aHCT marginally improved EFS rates. Another Italian study included 24 patients with relapsed HD who had FDG-PET performed after two cycles of salvage chemotherapy IGEV (ifosfamide, gemcitabine, vinorelbine, prednisone) before aHCT. The 2-year PFS was 93% for FDG-PET-negative and 10% for FDG-PET-positive patients [52]. Similar results were reported by investigators at Washington University in 46 patients with relapsed/refractory HD [53]. The pre-aHCT FDG-PET response significantly predicted 3-year EFS: 82% for FDG-PET-negative versus 41% for FDG-PET-positive patients ($p = 0.02$).

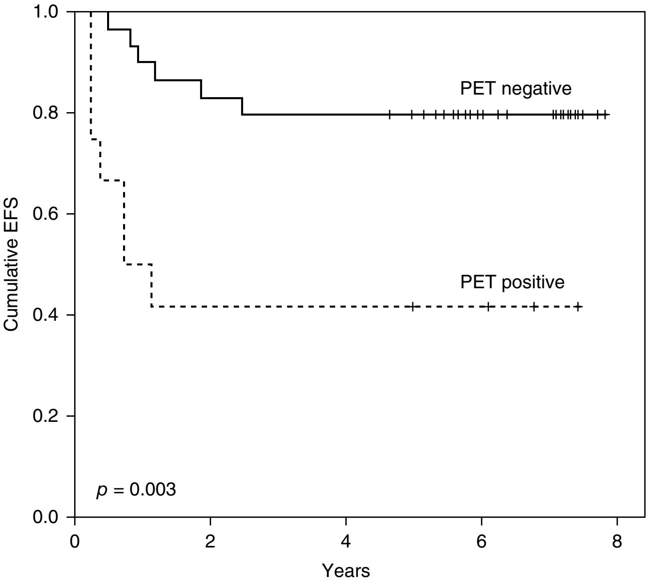

Figure 56.4 Event-free survival according to functioning image (FDG-PET) status before transplantation. Source: Moskowitz et al. 2010 [51]. Reproduced with permission of the American Society of Hematology.

These results suggest that a negative FDG-PET is associated with better outcome after aHCT, and alternative salvage therapy, investigational therapy, or post-transplant therapy may need to be considered for those with positive FDG-PET pre-transplant. This concept was tested at MSKCC in a phase II risk-adapted approach using presalvage risk factors (remission duration <1 year, B symptoms, and extranodal sites of disease)and also FDG-PET response to determine whether additional therapy was warranted before HDT and aHCT [51]. Patients with two risk factors were given two cycles of augmented ICE followed by restaging with FDG-PET. Patients with a negative scan received a transplant whereas those with positive FDG-PET received a non-cross-resistant chemotherapy GVD (gemcitabine, vinorelbine, and liposomal doxorubicin) regimen administered every 2 weeks for four doses. Patients without evidence of disease progression proceeded to HDT and aHCT; those with progressive disease were taken off the study. At a median follow-up of 51 months, patients with negative FDG-PET transplanted after one or two salvage programs had an EFS of >80% compared ith 28.6% for patients with a positive scan ($p < 0.001$).
